PREFACE

The editors are pleased to introduce *Van Nostrand's Scientific Encyclopedia*, Tenth Edition, thus building upon the long tradition of excellence that dates back some seventy years to the First Edition, published in 1938 as a single volume over 1,200 pages and updated over the decades in one volume (1947, 1958, 1968, 1976, 1983), and then in two volumes (1989, 1995, 2002). This Tenth Edition, in response to exponential growth, both in scientific knowledge and in the electronic availability of that knowledge, has grown perforce to three volumes over 6,100 pages.

The essence of *VNSE* is enduring, and it remains a fine, concise, comprehensive, and accessible general science work. Its intellectual scope ranges from the introductory to the highly technical in a vast and ever-expanding array of topical coverage in the sciences, engineering, mathematics, medicine, and more. As has long been the case, the editors have designed the book to be approachable by students of many ages. An important feature continued in this work, therefore, is the progressive development of the discussion of each topic, beginning with a simple definition expressed in plain terms, developing into a more detailed treatment, and augmented by often-extensive Additional Reading suggestions.

Contemporary readers can continue to turn to *VNSE* for information about how their daily lives are increasingly affected by the sophistication of today's science and the complexity of modern technology. They will be reminded that knowledge and discovery exist in a continuum, and that often, but not always, what is new depends entirely on what came before. As our esteemed, late editor of more than 30 years, Douglas M. Considine, was wont to say, "Science is history". With that mantra in mind, and noting that it has already been six years since the Ninth Edition in 2002, it is time to examine this new edition.

The five major changes noted in the Preface to the Ninth Edition are still very much a part of the book and are likely to remain so. First, the way that the editors wrote, gathered and assembled articles for this book is almost entirely electronic — from query letters to individuals or to academic, industrial or technical societies or entities; to primary research for new entries and updates for mature ones, now conducted almost entirely on the Internet; to communication between editor and publisher and the transmission of text between them in the partnership that results in the book itself. Second, the mushrooming Age of Discovery is still very much with us and is reflected in updates to articles and families of articles, with special emphasis on the many life sciences, space science, and computer technology, and much, much more, necessitating the expansion to a third volume. Third, the use of Internet references as Additional Reading suggestions, a groundbreaking feature of the Ninth edition, has been retained and expanded; even print articles are often archived electronically by magazines and journals and thus the quest for additional material is increasingly electronic in nature, with readers having the advantage of much of the culling of thousands of "hits" on a given topic having been done for them by the editors. Fourth, the editors have inculcated the previously new feature of Time Lines and Glossaries, to add at-a-glance information and historical perspective, into a staple of the book; new coverage includes virology, physiology, pharmaceuticals, the Internet, weather technology, and more. And fifth, the sense of history is further developed by expansion of another once-new feature, brief biographies of many influential scientists including many Nobel Prize winners in Medicine, Chemistry, and Physics; a history of their times is not complete without mention of their works. Science *is* history.

A statistical summary of the Tenth Edition would include more than 10,000 entries and 9,500 cross-references; 4,800 diagrams, graphs, and photographs; more than 600 tables; and an alphabetical Index of more than 100 printed pages that finds few rivals in the realm of technical literature. These are large increases, staggering particularly in the number of entries, and they are the result of an exhaustive, ongoing selection process for content perhaps best described so presciently by Douglas Considine in the Preface to the Sixth Edition in 1983: "Obviously, an encyclopedia of this type cannot serve the same purpose as a news medium. Science, too, has its own noise level. This is particularly evident from the hundreds of prematurely announced and exaggerated claims one frequently finds in the general communications media. Consequently, the authors and editors of this encyclopedia must carefully sift through the vast scientific data bank and sort out the trivia from real progress... there is no room for rumor and the untried and very little room indeed for the controversial in a permanent scientific reference such as this." To which the present editors say, Amen. But even the strictest selection criteria, applied to the gargantuan growth of knowledge, lead inevitably to the paradox that in print, what is new today will be, if not obsolete, at least in need of immediate updating tomorrow. To that end the editors have included thousands of Internet references to foster contemporaneity in research and Additional Reading. And further to that end, the editors have a wonderful announcement.

Van Nostrand's Scientific Encyclopedia, Tenth Edition, is now available on the Internet through the Wiley Interscience website. The online version uses embedded Internet references as hyperlinks both within the book itself and without — to the greater online community and also to other titles owned by John Wiley and Sons. At the click of a mouse the student or reader can now navigate VNSE instantly; this reflects how modern students actually pursue knowledge, and their parents are not far behind. The possibilities for ready acquisition of topical knowledge in, simply put, what is known, thus grow logarithmically through the interconnectedness of the VNSE and its links to the cyberworld. The editors feel strongly that, while there will always be an important place for printed literature of all kinds, as evidenced by the beautiful volumes at hand, the realm of scientific knowledge, compelled by the ongoing effects of that knowledge itself as expressed through information technology, will be accessed increasingly via electronic means.

In closing, one trusts that the reader will indulge a personal observation. In 1976 at the age of 61, Douglas M. Considine wrote and edited the Fifth Edition of *VNSE*. In 2008 at a similar age, his son Glenn D. Considine, also a writer and editor, presents the Tenth Edition of *VNSE*. Science is history. Family is history, too. Thus, this book is dedicated with abiding affection and gratitude to Douglas M. Considine.

ACKNOWLEDGMENTS

Specialists in all disciplines of the scientific community have contributed in many ways to the preparation of this Tenth Edition of the *Van Nostrand's Scientific Encyclopedia.* Their inputs ranged from the preparation of manuscripts on complex topics, the submittal of new data for the first time, advice and counsel to the Editorial Board, the seeking out of obscure and discrete information, and the reporting of research findings. Inputs represent those of scientists, engineers, technologists, located worldwide. In addition to numerous academic institutions and private industries, the editors are much indebted to numerous governmental departments, agencies, and field organizations for their cooperation. It has always been in the best tradition of the history of science to share knowledge. It is therefore no mere coincidence that so many contributors are teachers at the university level, for they not only have deep knowledge in their respective fields, but they also can communicate that knowledge effectively. The great improvements to the substance of this book would not have been possible without them, and the editors have preserved the individual styles of the authors in keeping with the tradition of *VNSE* as an eminently personal, and, one hopes, more accessible work of general science. The editors and staff of this encyclopedia gratefully acknowledge their excellent cooperation and stress that the following abridged list of over 650 individuals and groups could be much longer.

Special appreciation must be extended for the efforts of Michael Ladisch of Purdue University, for his home article on Bioprocess Engineering (Biotechnology). — David Leake of Indiana University, both for his home article on Artificial Intelligence, and for quarterbacking the entire family of twelve AI "sidebar" articles. — The American Meteorological Society for their gracious permission to use numerous articles from the glossary of meteorology. — Ramon A. Mata-Toledo, *James Madison University*, who reviewed the Computer Sciences and authored several articles. — Joseph Castellano, President and CEO of *Stanford Resources*, who prepared numerous entries on Flat Panel Display Technology. — Dr. Thomas J. Harrison, who prepared numerous articles on computers and digital technology. — Dr. Steven N. Shore, who authored and arranged several entries dealing with astronomy and related sciences. — Dr. Ann C. DeBaldo, University of South Florida, who prepared numerous entries in the areas of immunology, oncology, and infectious diseases. — Drs. M. L. and W. L. Dilling, who skillfully summarized the complex world of organic chemistry, its nomenclature and equations. — Richard Q. Hofacker Jr., who authored articles on microelectronics and telephony and who rendered invaluable assistance toward creating comprehensive, yet concise, inputs concerning the broad field of telecommunications. — Peter E. Kraght, who not only authored several articles, but who also prepared the foundation for other descriptions in the spheres of meteorology and climatology. — Elmer Rowley, who made the coverage of mineralogy and crystallography in this encyclopedia truly outstanding. — *VisionRx*, Elmsford, NY., for the numerous entries on Vision and eye related disorders. — Jeanne Maree Iacono, who authored and rendered invaluable assistance toward creating brief biographies on scores of scientists. Without exaggeration, the list of such very special efforts could be extended by several additional paragraphs.

NOTE: In the cases of relatively short articles, the authors' initials may be used instead of their full names. In the following list, an asterisk indicates such authors. For example: *American Meteorological Society (AMS).

A

AA. An Hawaiian term introduced into geological nomenclature by C.E. Dutton in 1883, and signifying the jagged, scoriaceous, blocky and exceedingly rough surface of some basic lava flows. Prounced *ah-ah*.

AAAS. The American Association for the Advancement of Science was founded in 1848 and incorporated in 1874. Its objectives are to further the work of scientists, to facilitate cooperation among them, to foster scientific freedom and responsibility, to improve the effectiveness of science in promoting human welfare, to advance education in science, and to increase public understanding and appreciation for the importance and promise of the methods of science in human progress. The AAAS head quarters is in Washington, DC. Additional information on the AAAS can be found at *http://www.aaas.org/* and *http://www.sciencemag.org/*.

AAC (ADVANCED AUDIO CODING). See **Data Compression**.

AARDVARK *(Mammalia, Tubulidentata).* African animals of peculiar form and ancient lineage, including an Ethiopian and a South African species. All are anteaters, feeding exclusively on ants and termites, nocturnal in habit, with acute hearing. The southern species has been called the ant bear. The aardvark is the only living representative of its order. The animal's spine, curved from neck to tail in a near-half circle, gives it a truly prehistoric appearance.

The aardvark is solitary. In daytime it sleeps curled up like a dog in one of its burrows, often beneath a termite hill. The animal moves almost entirely at night, when it seeks termite hills and destroys them to reach the interior chambers and tunnels alive with insects, which it rapidly licks up in lumps. Although usually silent, the animal can grunt like a hippopotamus. Life span is at least 10 years. In captivity, aardvarks become accustomed to keepers, but do not show great intelligence. See Fig. 1.

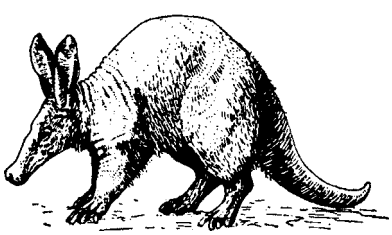

Fig. 1. The habitus or body definitely purveys a pig-like appearance.

AARDWOLF *(Mammalia, Carnivora).* An African species, *Proteles cristatus,* superficially like the striped hyena, not common, nocturnal and sleeps by day under termite nests or in excavated or aard-vark holes. Teeth reduced in number and size, and insect eater, but can chew very rotten meat or newly born animals. See also **Hyena**.

ABACA. The sclerenchyma bundles from the sheathing leaf bases of *Musa textilis,* a plant closely resembling the edible banana plant. These bundles are stripped by hand, after which they are cleaned by drawing over a rough knife. The fiber bundles are now whitish and lustrous, and from six to twelve feet (1.8–3.6 meters) long. Being coarse, extremely strong and capable of resisting tension, they are much used in the manufacture of ropes and cables. Since the fibers swell only slightly when wet, they are particularly suited for rope that will be used in water. Waste manila fibers from rope manufacture and other sources are used in the making of a very tough grade of paper, known as manilla paper. The fibers may be obtained from both wild and cultivated plants, the latter yielding a product of better grade. The cultivated plants, propagated by seeds, by cuttings of the thick *rhizomes* or by suckers, are ready for harvest at the end of three years, after which a crop may be expected approximately every three years.

ABALONE *(Mollusca, Gasteropoda; Haliotis).* Marine species, usually found in the Pacific and Indian Oceans. The single broad shallow shell has a richly colored iridescent inner surface and is an important source of mother-of-pearl and blister pearls for costume jewelry. The flesh is palatable.

The few whorls of abalone shells are flattened and rapidly increase in diameter so that the largest part of the shell consists of the last part of the whorl (*ear-form*). The European representative of this family is the *Ormer* (*Haliotis tuberculata*), which is characterized by knotty longitudinal shell ridges. It is distributed from the English Channel to western Africa. *Haliotis tuberculata* lamellosa (Fig. 1.) is characterized by transverse shell ridges. Both forms usually measure 2 to 3 inches (5 to 7 centimeters). The largest species occur along the Pacific Coast of the United States, in northern Japan, and in southern Australia, where the animals are commercially fished for their delicious meat. The iridescent shells are used extensively in making jewelry. Most of the approximately seventy species are found in cool waters. Some members of this group attain shell lengths of over 8 inches (20 centimeters) and live to an age of 10 to 13 years. Aside from the characteristics already mentioned, abalone are further unique in that the slit band is present only as a series of small holes. During further growth, abalone develop additional holes in a curved line, and the "retired" holes are sealed over.

The abalone inhabiting the intertidal zone to a depth of about 164 feet (50 meters) scrape algae off rocks. All abalone species have adapted to this ecological niche by developing a broad suction foot with a correspondingly large shell. The light-shunning animals attach themselves to shady parts of the rock with this broad foot. The suction force of this foot is more than 4000 times that of the animal's body weight. See also **Mollusks**.

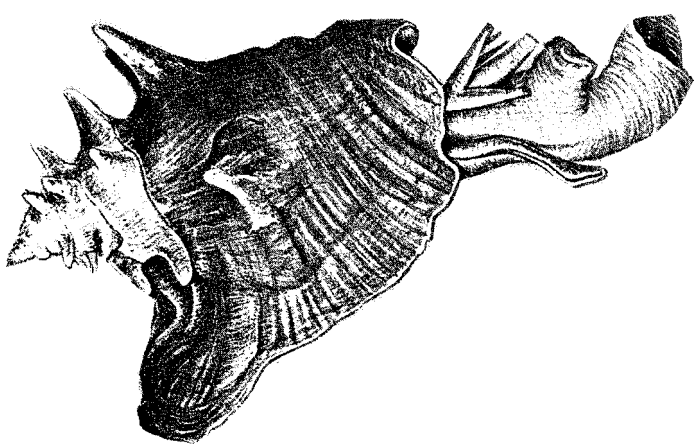

Fig. 1. Abalone (*Haliotis tuberculata lamellosa*), characterized by transverse shell ridges.

ABATEMENT. See **Meteorology**.

ABBE CONDENSER. A compound lens used for directing light through the object of a compound microscope. All the light enters the object at an angle with the axis of the microscope. See also **Microscope (Traditional-Optical)**.

ABBE NUMBER. The reciprocal of the dispersive power of a material. It is also called the v-number.

ABBE SINE CONDITION. The relationship

$$ny \sin\theta = n'y' \sin\theta',$$

where n, n' are refractive indices, y, y' are distances from optical axis, and θ, θ' are angles light rays make with the optical axis. A failure of an optical surface to satisfy the sine condition is a measure of the coma of the surface.

ABDOMEN. The abdomen is the posterior division of the body in many arthropods. It is the *posterior* portion of the trunk in vertebrates. In the vertebrates this region of the body contains most of the alimentary tract, the excretory system, and the reproductive organs. It contains part of the coelom and in mammals is separated from the thorax by the diaphragm.

The abdominal cavity of the human body is subdivided into the abdomen proper and the pelvic cavity.

The walls of the abdominal cavity are lined with a smooth membrane called the peritoneum, which also provides partial or complete covering for the organs within the cavity.

The abdomen proper is bounded above by the diaphragm; below it is continuous with the pelvic cavity; at the posterior it is bounded by the spinal column, and the back muscles; and on each side by muscles and the lower portion of the ribs. In front, the abdominal wall is made up of layers of fascia and muscles. The abdomen is divided into nine regions whose boundaries may be indicated by lines drawn on the surface. The mid-section above the navel between the angle of the ribs is known as the epigastric region; that portion around the navel, as the umbilical; below the navel and above the pubic bone, as the hypogastric region. It is further divided into right and left upper quadrants on each side above the navel, and right and left lower quadrants on each side below the navel. The lumbar region extends on either side of the navel to the posterior and laterally.

The principal organs of the abdominal cavity are the stomach, duodenum, jejunum, ileum, and colon or large intestine, the liver, gall bladder and biliary system, the spleen, pancreas and their blood and lymphatic vessels, lymph glands, and nerves, the kidneys and ureter.

The pelvic portion of the abdomen contains the sigmoid colon and rectum, a portion of the small intestine, the bladder, in the male the prostate gland and seminal vesicles, in the female the uterus, Fallopian tubes, and ovaries.

ABEL EQUATION. A mass point moves along a smooth curve in a vertical plane and under the influence of gravity alone. Given the time, t, required for the particle to fall from a point, x, to the lowest point on the curve as a function of x, what is the equation of the curve? The problem leads to a Volterra integral equation of the first kind.

$$f(x) = \int_0^x \frac{\phi(t)\,dt}{\sqrt{2g(x-t)}}$$

where g is the acceleration of gravity. The solution is

$$\phi(x) = \frac{\sqrt{2g}}{\pi} \int_0^x \frac{f'(t)\,dt}{\sqrt{x-t}}$$

and the equation of the curve is

$$y = \int_0^x \sqrt{|\phi^2(t) - 1|\,dt}$$

A closely related problem is that of the brachistochrone, where the path is required for a minimum time of descent. Such matters were of considerable interest to many seventeenth and eighteenth century mathematicians; the one described here was solved by the Norwegian, N.H. Abel (1802–1829). See also **Brachistochrone**.

A more general case of the Abel equation is

$$f(x) = \int_0^x (x-y)^{-\alpha} \phi(y)\,dy$$

where $f(x)$ is continuously differentiable for $x \geq 0$ and $0 < \alpha < 1$. The solution is

$$\phi(y) = \frac{\sin\alpha\pi}{\pi} \left[\int_0^y (y-x)^{\alpha-1} f'(x)\,dx + f(0)y^{\alpha-1} \right]$$

ABELIAN GROUP. A commutative group, namely such that $AB = BA$ where A, B are any two elements contained in it.

ABERRATION OF LIGHT. The apparent change of position of an object, due to the speed of motion of the observer. Care must be taken not to confuse this effect with that of parallax.

If a telescope, assumed to be stationary, is pointed at a source of light, the light that enters the object glass centrally and in the direction of the optic axis will pass through the telescope along that axis and emerge through the center of the eyepiece. If the telescope is in motion relative to the source, in any direction other than parallel to the optic axis, the light that enters centrally will emerge off the center of the eyepiece. If this light is to emerge centrally, the telescope must be tilted forward in the plane containing the direction of motion of the instrument and the source. The amount of tilt will depend on the direction of the source and the ratio of the speed of the telescope to the speed of light.

This aberrant effect was first announced by Bradley in 1726. He noticed that stars had apparent periodic motions with a period of one sidereal year, and that the character of the apparent motion depended upon the celestial latitude of the star. He correctly interpreted the effect as due to the motion of the earth about the sun. Statistical discussions of the observations of a large number of stars have shown that the maximum value of this aberration due to the earth's orbital motion is $20''.47$. This is known as the "aberration angle" or the "constant of aberration," and is given by

$$\kappa = \frac{2\pi a \operatorname{cosec} 1''}{cT(1-e^2)^{1/2}}$$

where a is the mean radius of the earth's orbit, c is the velocity of light, T is the length of the year in seconds, and e is the eccentricity of the orbit. An aberrational effect of about $0''.3$, at maximum, is observed, due to the rotation of the earth on its axis, and is given by

$$k = \frac{2\pi\rho \cos\phi \operatorname{cosec} 1''}{ct}$$

where ρ is the radius of the earth, ϕ is the latitude of the place, and t is the length of the day in seconds.

In 1871, Airy made a series of observations for determination of the aberration constant, using a telescope filled with water. Because the value of the index of refraction of water is about $1\frac{1}{3}$, Airy expected that the value of the aberration would be $27''.3$ when using the water-filled tube. He found, however, that the value was $20''.5$ no matter what substance was placed in the telescope. The result of this so-called "Airy's Experiment" caused much discussion, but was eventually explained on the basis of the Michelson-Morley experiment and the theory of relativity.

All observations in which the positions of the stars are involved must be corrected for aberration of light if the results are to be accurate to within $20''$. Both the motion of the earth about the sun and the rotation of the earth must be considered. The magnitude of the correction depends upon the celestial coordinates of the star, the position of the observer on the earth, and the date and time of observation.

ABERRATION (Optical). The failure of an optical system to form an image of a point as a point, of a straight line as a straight line, and of an angle as an equal angle. See also **Astigmatism**; **Chromatic Aberration**; **Coma (Optics)**; **Curvature of Field (Optics)**; and **Spherical Aberration**.

ABHERENT. Any substance that prevents adhesion of a material to itself or to another material. It may be in the form of a dry powder (a silicate such as talc, mica, or diatomaceous earth); a suspension (bentonite–water); a solution (soap–water); or a soft solid (stearic acid, tallow waxes). Abherents are used as dusting agents and mold washes in the adhesives, rubber, and plastics industries. Fats and oils are used as abherents in the baking industry. Fluorocarbon resin coatings on metals are widely used on

cooking utensils. See also **Adhesives**, **Plastics**, **Plastics Processing** and **Release Agents**.

ABLATE. To carry away; specifically, to carry away heat generated by aerodynamic heating, from a vital part, by arranging for its absorption in a nonvital part, which may melt or vaporize, then fall away taking the heat with it. See also **Heat Shield**; and **Ablation**.

ABLATING MATERIAL. A material, especially a coating material, designed to provide thermal protection to a body in a fluid stream through loss of mass. Ablating materials are used on the surfaces of some reentry vehicles to absorb heat by removal of mass, thus blocking the transfer of heat to the rest of the vehicle and maintaining temperatures within design limits. Ablating materials absorb heat by increasing in temperature and changing in chemical or physical state. The heat is carried away from the surface by a loss of mass (liquid or vapor). The departing mass also blocks part of the convective heat transfer to the remaining material in the same manner as transpiration cooling. See also **Ablative Materials**.

ABLATING NOSE CONE. A nose cone designed to reduce heat transfer to the internal structure by the use of an ablating material.

ABLATION. The removal of surface material from a body by vaporization, melting, chipping, or other erosive process; specifically, the intentional removal of material from a nose cone or spacecraft during high-speed movement through a planetary atmosphere to provide thermal protection to the underlying structure. See also **Ablatine Materials**.

ABLATION (Geomorphology). Essentially, the wasting away of rocks; the separation of rock material and formation of residual deposits, as caused by wind action or the washing away of loose and soluble materials.

ABLATION (Glaciology). The combined processes (sublimation, melting, evaporation) by which snow or ice is removed from the surface of a glacier or snowfield. In this sense, the opposite of alimentation. Ablation also refers to the amount of snow or ice removed by the aforementioned processes (the opposite of accumulation). The term may be applied to reduction of the entire snow-ice mass, and may also include losses by wind action and by calving (the breaking off of ice masses). Air temperature is the dominant factor in controlling ablation. During the ablation season, an ablation rate of about two millimeters/hour is typical of most glaciers. An ablatograph is an instrument that measures the distance through which the surface of snow, ice, or firn moves, as caused by ablation, during a specific period.

ABLATION (Meteorite). The direct vaporization of molten surface layers of meteorites and tektites during flight.

ABLATION (Spacecraft). In the interest of cooling space vehicles upon reentry into the earth's atmosphere, ablation is used to control the temperature of strongly heated surfaces, such as parts of combustion chambers or nose cones. The process usually consists of the use of surface layers of materials that by their fusion, followed often by evaporation, absorb heat.

The heat of ablation is a measure of the effective heat capacity of an ablating material. Numerically, this is the heating rate input divided by the mass loss rate that results from ablation. In the most general case, heat of ablation is given by

$$(q_c + q_r - \sigma \varepsilon T_w^4)/\mathring{\mathrm{m}}$$

where q_c is the convective heat transfer in the absence of ablation; q_r is the radiative heat transfer from hot gases to ablation material; $\sigma \in T_w^4$ is the rate of heat rejection by radiation from external surface of ablation material; and $\mathring{\mathrm{m}}$ is rate at which gaseous ablation products are injected into the boundary layer.

Heat of ablation is sometimes evaluated neglecting the heat rejected by radiation and as a result unrealistically high heats of ablation are obtained.

If $q_r < \sigma \in T_w^4$, for moderate values of stream enthalpy h_s, the heat of ablation is given by

$$H_v + \eta(h_s - h_w)$$

where H_v is the heat required to cause a unit weight of mass to be injected into boundary layer; η is the blocking factor, with numerical value from about 0.2 to 0.6 depending on material and type of flow; and h_w is the enthalpy at wall temperature.

ABLATIVE MATERIALS. The word ablation is derived from the suppletive past particle of the Latin *auferre*, which means to remove. It was originally used in the geologic sense to describe the combined, predominantly thermal, processes by which a glacier wastes. The present use of the word maintains the thermal aspect and describes the absorption, dissipation, and blockage of heat associated with high speed entry into the atmosphere. Thus ablative, thermal protection materials are used to protect vehicles from damage during atmospheric reentry. The need for these materials was first realized during the development of operational ballistic missiles in Pennemunde, Germany, when a large percentage of V-2s failed to reach their targets because of missile skin disintegration caused by aerodynamic heating. Ablative materials are also used to protect rocket nozzles and ship hulls from propellant gas erosion, as protection from laser beams, and to protect land-based structures from high heat environments.

The functional requirements of the ablative heatshield must be well understood before selection of the proper material can occur. Ablative heatshield materials not only protect a vehicle from excessive heating, they also act as an aerodynamic body and sometimes as a structural component. Intensity and duration of heating, thermostructural requirements and shape stability, potential for particle erosion, weight limitations, and reusability are some of the factors which must be considered in selection of an ablative material.

Some typical ablative environments include Jet aircraft, space shuttle, long range balistic muscles, etc. Each of the altitude−velocity profiles results in a specific heating rate and radiation equilibrium temperature for a given material. When a vehicle decelerates at high altitudes under low pressure conditions, and the flight angle with respect to the horizon is low, the heating rate is low but the heating time period is long, e.g., the Apollo trajectory. In this situation, material insulating ability becomes important. Conversely, a sharp atmospheric entry angle results in severe heating rates but for a shorter duration, e.g., the ballistic missile trajectory, which requires less emphasis on the insulating capability of the heatshield material.

Several other factors must also be considered with respect to heating conditions. At the front end of a vehicle, i.e. at the nosetip, the heating rate is most severe, generally decreasing toward the aft end of the vehicle in instances of laminar flow. Because of this variation in heating conditions, the nosetip material is usually different from the heatshield or aft end materials. Vehicle design is, of course, influential. Sharp, heavy ballistic vehicles having a high mass-to-drag ratio drop in altitude at higher velocities than blunt, lightweight Apollo-type vehicles, resulting in much higher heating rates for the former. Then also, efficient aerodynamic vehicles, such as long range glide vehicles, utilize sharp leading edges on the nose and wings at the expense of high local heating. Moreover, the rate of heat transfer for a turbulent gas boundary results in higher heating conditions than a laminar gas stream. Thus to reduce or delay the tendency for turbulent flow, smooth, uniform vehicle contours are preferred and, whenever possible, high density materials are avoided to minimize the weight-to-drag ratio.

Heatshield thickness and weight requirements are determined using a thermal prediction model based on measured thermophysical properties. The models typically include transient heat conduction, surface ablation, and charring in a heatshield having multiple sublayers such as bond, insulation, and substructure. These models can then be employed for any specific heating environment to determine material thickness requirements and to identify the lightest heatshield materials.

In a very simplified first-order analysis the ablative heatshield is considered to be of two components: the ablated thickness and the remaining thickness, or the insulation.

The selection of a material having the right balance of ablation and insulation properties is needed to produce optimum heatshield performance. This material selection is complicated because the higher density materials that usually offer better ablation performance also have higher thermal conductivities and are therefore poor insulators. Properties of known materials are given in Table 1.

The thermostructural requirements of the heatshield are important to material selection and both aerodynamic and attachment load requirements

TABLE 1. HEAT OF ABLATION AND RELATIVE THERMAL CONDUCTIVITY FOR REENTRY VEHICLE MATERIALS ASSUMING LAMINAR FLOW

Material	Cold wall heat of ablation[a], J/g[b] $H_s = 12{,}000$ J/g $V_\infty = 4800$ m/s	Cold wall heat of ablation[a], J/g[b] $H_s = 24{,}000$ J/g $V_\infty = 6{,}800$ m/s	Relative thermal conductivity
Carbon–carbon	32,000	39,500	high
Carbon–phenolic	24,000	29,600	
Silica–phenolic	13,000	19,000	
Teflon	6,650	10,350	low

[b] To convert J to cal divide by 4.184.

must be met. In the case of a charring ablator, surface char must be of sufficient strength to survive aerodynamic shear. Changes in the ablative material's mechanical and thermal properties occur as a result of the thermal gradient through the depth of the material. Backface surface temperatures, the temperatures on the inside surface of the heatshield, dictate attachment methods and materials. An excessive backface surface temperature caused by inadequate insulation characteristics may weaken an adhesive bond to a substructure or even weaken a load-carrying substructure. In the event that the heatshield also serves as the load-carrying structure, sufficient thickness must be provided for both ablation and insulation so that enough material remains cold (uncharred). A mismatch in axial vs radial thermal expansion can result in severe thermal stresses and subsequent failure, as has been noted with the use of thick sections of pyrolitic graphite [CAS: 7782-42-5]. In reentry, erosion from rain or ice particles is also a consideration, particularly at the tip. In addition, in rocket nozzles and on surfaces exposed to propellant gases, erosion resistance from solid particulates must also be considered.

The practice of employing reusable thermal protection systems for reentry is becoming more common. These are essentially ablative materials exposed to environments where very little ablation actually occurs.

Another environmental issue important to low earth orbit materials is atomic erosion. At an altitude of 300 km (186 miles), absorption of solar radiation produces atmospheric temperatures of 1150 °C (2102 °F), and at these temperatures gas molecules decompose. Erosion of surface materials by oxygen atoms or nitrogen–oxygen radicals is a serious issue for low altitude orbiting satellites. Experiments conducted on early shuttle flights determined that organic materials that would normally be found on a heatshield erode more rapidly than metallic ones. Thus, the effects of atomic erosion must be considered for any vehicle that is subject to long term exposure at low earth altitudes See **Space Shuttle**.

A variety of test methods and facilities have been developed to address the process of ablation. These utilize lasers, chemical flames, plasma arcs, electric arc heaters, and other heat sources and sometimes include high velocity wind tunnel facilities that introduce particles to simulate high speed erosion.

Ablation Process

Thermophysically, the ablation process can be described as the elimination of a large amount of thermal energy by sacrifice of surface material. Principles operating during this highly efficient and orderly heat and mass transfer process are (*1*) phase changes such as melting, vaporization, and sublimation, (*2*) conduction and storage of heat in the material substrate, (*3*) absorption of heat by gases as they are forced to the surface, (*4*) heat convection in a liquid layer, (*5*) transpiration of gases and liquids and subsequent heat absorption from the surface into the boundary layer, (*6*) exothermic and endothermic chemical reactions, and (*7*) radiation on the surface and in bulk.

The relationship between heat transfer and the boundary layer species distribution should be emphasized. As vaporization occurs, chemical species are transported to the boundary layer and act to cool by transpiration. These gaseous products may undergo additional thermochemical reactions with the boundary-layer gas, further impacting heat transfer. Thus species concentrations are needed for accurate calculation of transport properties, as well as for calculations of convective heating and radiative transport.

Ablative Materials

Ablative materials are classified according to dominant ablation mechanism. There are three groups: subliming or melting ablators, e.g., graphite, Carbon–carbon composites, and ceramic ablators charring ablators used in combination with subliming or meeting reenforcement materials, e.g., Carbon-fiber reenforced phenolic composites, silicone elastomer, and intumescent ablators generally not used on searce environments, they form a surface char, Figure 1 shows the physical zones of each. Because of the basic thermal and physical differences, the classes of ablative materials are used in different types of applications.

ABNEY EFFECT. A shift in hue which is the result of a variation in purity and, therefore, in saturation. The Abney effect may be represented by chromaticity loci, of specified luminance, with the hue and brightness constant, when purity and, therefore, saturation are varied. It is a relationship, of psychophysical nature, between psychophysical specifications and color sensation attributes.

ABRASION. All metallic and nonmetallic surfaces, no matter how smooth, consist of minute serrations and ridges that induce a cutting or tearing action when two surfaces in contact move with respect to each other. This wearing of the surfaces is termed abrasion. Undesirable abrasion may occur in bearings and other machine elements, but abrasion is also adapted to surface finishing and machining, where the material is too hard to be cut by other means, or where precision is a primary requisite.

ABRASION pH. A term originated by Stevens and Carron in 1948 "to designate the pH values obtained by grinding minerals in water." Abrasion pH measurements are useful in the field identification of minerals. The pH values range from 1 for ferric sulfate minerals, such as coquimbite, konelite, and rhomboclase, to 12 for calcium-sodium carbonates, such as gaylussite, pirssonite, and shortite. The recommended technique for determining abrasion pH is to grind, in a nonreactive mortar, a small amount of the mineral in a few drops of water for about one minute. Usually, a pH test paper is used. Values obtained in this manner are given in the middle column of Table 1. Another method, proposed by Keller et al. in 1963, involves the grinding of 10 grams of crushed mineral in 100 milliliters of water and noting the pH of the resulting slurry electronically. Values obtained in this manner are given in the right-hand column.

TABLE 1. ABRASION pH VALUES OF REPRESENTATIVE MINERALS

Mineral	pH by Stevens-Carron Method	pH by Keller et al. Method
Coquimbite	1	
Melanterite	2	
Alum	3	
Glauconite	5	5.5[a]
Kaolinite	5, 6, 7	5.5[a]

ABRASIVES. An abrasive is a substance used to abrade, smooth, or polish an object. If the object is soft, such as wood, then relatively soft abrasive materials may be used. Usually, however, abrasive connotes very hard substances ranging from naturally occurring sands to the hardest material known, diamond.

Abrasives were literally as old or older than the Egyptian pyramids; in ancient times, humans used a variety of materials to refine or polish surfaces. For example, the Chinese used corncob skins for polishing. Shark skin, with its dermal denticles known as placoid scales, naturally provided abrasive properties. Humans also harvested the most common and abundant minerals in the earth's crust, namely, the quartz family of minerals. The ancient Greeks called quartz "crystal" and this quartz took the form of sandstone, loose sand, and flint. This crystal material was used in the abrading of stone, wood, metal and grinding grains, and limestone. Additionally, the ancient Greeks developed the use of corundum (naturally occurring aluminum oxide) and garnet, which were superior to quartz. Other abrasive materials known were hematite, now known as Jeweler's rouge, in 325 BC by Theophratus. Diamond as a polishing material was referenced in India in 800 BC and its exceptional hardness was referred to in ancient Hindu proverbs and in the Bible.

During the Industrial Revolution of the 1800s, the development of abrasive articles went hand in hand with the metal-working industry. In early years, sandstone rocks were mined out of the earth and carved into grinding wheels. Flint and naturally occurring corundum were bonded to paper to form sandpaper. The abrasive grains used were primarily mined materials such as sandstone, quartz, naturally occurring corundum, and garnet. These minerals had significant amounts of impurities, including iron, silica, and silicates, which lowered their abrasive grain hardness and hindered their performance. During the late 1800s, and early 1900s, synthetically manufactured abrasive grains revolutionized the abrasive industry. The synthetic abrasives tended to be harder, tougher and purer than mined abrasive grains. Edward Acheson is credited with inventing synthesized silicon carbide in 1891. Excluding diamond, silicon carbide

was the hardest abrasive grain available for years to come. Even today, silicon carbide is produced under essentially the same process and furnace that Acheson invented. The silicon source (typically from very pure sand) and carbon source (usually graphite) are reacted at temperatures in excess of 2000 °C to cause the reduction of silica by carbon.

Around the turn of the twentieth century, synthetically manufactured fused alumina was invented. In this process, alumina-based raw materials are heated above its melting point, typically ∼2000 °C, and subsequently cooled to form fused alumina. This basic process was originally patented by Werlein in France in 1893 and by Hasslacher in Germany in 1894. This process was further advanced by C. M. Hall through the addition of iron borings into the fusion melt to remove metallic impurities. The resulting aluminous abrasive grain was purer. A. C. Higgins then developed an improved furnace design that involved the use of a water-cooled shell container. This new furnace design used a solid, thin alumina coating on the furnace walls that prevented the molten alumina from attacking the steel furnace walls. This basic Higgins furnace design is still widely used today in manufacturing many fused alumina grains.

Over these multitude of centuries, abrasive articles were employed, quite simply, to change a surface. These abrasive articles relied on a broad range of technologies including ceramics, inorganic chemistry, paper, textiles, organic chemistry, polymer science, and related process technologies. During the past 150 years, as these technologies grew, so did the advancement of abrasive technologies to create abrasive articles with even higher efficiencies.

There are three basic forms of abrasives: grit (loose, granular, or powdered particles); bonded materials (particles are bonded into wheels, segments, or stick shapes); and coated materials (particles are bonded to paper, plastic, cloth, or metal).

Properties

The earliest scale was developed by the German mineralogist Friedrich Mohs in 1820. It is based on the relative scratch hardness of one mineral compared to another ranging from talc, assigned a value of 1, to diamond, assigned a value of 10. Mohs' scale has two limitations; it is not linear and, because most modern abrasives fall between 9 and 10, there is insufficient delineation. Ridgeway and co-workers modified Mohs' scale by giving garnet a hardness value of 10 (H = 10) and making diamond 15. Woodell extended the scale even further by using resistance to abrasion, where diamond equals 42.5. This method is dynamic and less affected by surface hardness variations than the other methods, which involve indentation.

Knoop developed an accepted method of measuring abrasive hardness using a diamond indenter of pyramidal shape and forcing it into the material to be evaluated with a fixed, often 100 g, load. The depth of penetration is then determined from the length and width of the indentation produced. Unlike Woodell's method, Knoop values are static and primarily measure resistance to plastic flow and surface deformation. Variables such as load, temperature, and environment, which affect determination of hardness by the Knoop procedure, have been examined in detail.

A linear relationship exists between the cohesive energy density of an abrasive and the Woodell wear resistance values occurring between corundum (H = 9) and diamond (H = 42.5). The cohesive energy density is a measure of the lattice energy per unit volume.

An abrasive's toughness is often measured and expressed as the degree of friability, the ability of an abrasive grit to withstand impact without cracking, spalling, or shattering.

Instantaneous grinding temperatures may exceed 3500 °C at the interface between an abrasive and the workpiece being ground. Hence melting temperature is an important property. Additionally, for alumina, silicon carbide, B_4C, and many other materials, hardness decreases rapidly with increasing temperature. Fortunately, ferrous metals also soften with increasing temperatures and do so even more rapidly than abrasives.

Any chemical interaction between abrasive grains and the material being abraded affects the abrasion process.

Abrasive materials may transfer heat from the cutting tip of the grain to the bond posts, retaining the heat in a bonded wheel or coated belt.

Fracture characteristics of abrasive materials are important, as well as the resulting grain shapes. Equiaxed grains are generally preferred for bonded abrasive products and sharp, acicular grains are preferred for coated ones. How the grains fracture in the grinding process determines the wear resistance and self-sharpening characteristics of the wheel or belt.

Crystal size, porosity, and impurity phases play a major role in fixing the fracture characteristics and toughness of an abrasive grain.

Classes of Abrasives

Natural Abrasives. Naturally occurring abrasives are still an important item of commerce, although synthetic abrasives now fill many of their former uses. They include diamonds, corundum, emery, garnet, silica, sandstone, tripoli, pumice, and pumicite.

Manufactured Abrasives. Manufactured abrasives include silicon carbide, fused aluminum oxide, sintered aluminum oxide, sol–gel sintered aluminum oxide, fused zirconia–alumina, synthetic diamond, cubic boron nitride, boron carbide, slags, steel shot, and grit.

Manufactured abrasives are produced in a variety of sizes that range from a pea-sized grit of 4 (5.2 mm) to submicrometer diameters. It is almost impossible to produce an abrasive grit that will just pass through one sieve size yet be 100% retained on the next smaller sieve. Thus a standard range was adopted in the United States that specifies a screen size through which 99.9% of the grit must pass, maximum oversize, minimum on-size, maximum through-size, and fines.

Screening is a two-dimensional (2D) process and cannot give information about the shape of the abrasive particle. Desired shapes are obtained

TABLE 1. SCALES OF HARDNESS

Material	Mohs' scale	Ridgeway's[a] scale	Woodell's[b] scale	Knoop hardness[c], kN/m^2,[d]

by controlling the method of crushing and by impacting or milling. Shape determinations are made optically and by measuring the loose-packed density of the abrasive particles; cubical-shaped particles pack more efficiently than acicular-shaped particles. In general, cubical particles are preferred for grinding wheels, whereas high aspect-ratio acicular particles are preferred for coated abrasive belts and disks.

Chemical analyses are done on all manufactured abrasives, as well as physical tests such as sieve analyses, specific gravity, impact strength, and loose poured density (a rough measure of particle shape). Special abrasives such as sintered sol–gel aluminas require more sophisticated tests such as electron microscope measurement of α-alumina crystal size, and indentation microhardness.

Coated Abrasives. Coated abrasives consist of a flexible backing on which films of adhesive hold a coating of abrasive grains. The backing may be paper, cloth, open-mesh cloth, vulcanized fiber (a specially treated cotton rag base paper), or any combination of these materials. The abrasives most generally used are fused aluminum oxide, sol–gel alumina, alumina–zirconia, silicon carbide, garnet, emery, and flint.

A new form of coated abrasive has been developed that consists of tiny aggregates of abrasive material in the form of hollow spheres. As these spheres break down in use, fresh cutting grains are exposed; this maintains cut-rate and keeps power low.

Bonded Abrasives. Grinding wheels are by far the most important bonded abrasive product both in production volume and utility. They are produced in grit sizes ranging from 4, for steel mill snagging wheels, to 1200, for polishing the surface of rotogravure rolls.

Grinding wheels and other bonded abrasive products are specified by a standard marking system that is used throughout most of the world. This system allows the user to recognize the type of abrasive, the size and shaping of the abrasive grit, and the relative amount and type of bonding material.

Most bonded abrasive products are produced with either a vitreous (glass or ceramic) or a resinoid (usually phenolic resin) bond.

Special forms of bonded abrasives include honing and superfinishing stones, pulpstone wheels, crush-form grinding wheels, and creep feed wheels.

Superabrasive Wheels. Superabrasive wheels include diamond wheels and cubic boron nitride (CBN) wheels.

Uses

Grinding fluids or coolants are fluids employed in grinding to cool the work being ground, to act as a lubricant, and to act as a grinding aid. Soluble oil coolants in which petroleum oils are emulsified in water have been developed to impart some lubricity along with rust-preventive properties.

In addition to their use in bonded and coated products, both natural and manufactured abrasive grains are used loose in such operations as polishing, buffing, lapping, pressure blasting, and barrel finishing.

High pressure jet cutting with abrasive grit can be used on metals to produce burn-free cuts with no thermal or mechanical distortion.

ABSAROKITE. A geologic term proposed by Iddings in 1805 for a porphyritic basalt containing phenocrysts of olivine and augite in a ground mass of smaller labradorite crystals. Type locality, Absaroka Range, Wyoming.

ABSCESS. A localized collection of pus within a cavity. An abscess may occur in many organs of the body. Abscesses can present a range of symptoms, depending upon location and cause, varying from severe, acute forms to milder, chronic forms.

White blood cells, the body's defense against some types of infection, migrate through the walls of the blood vessels, in the area of the infection and collect within the damaged tissue. During this process, "pus" forms, which is an accumulation of fluid, living and dead white blood cells, dead (necrotic) tissue, and bacteria or other foreign invaders or materials. The presence of an abscess is always considered a serious matter by a physician because without immediate treatment, very serious consequences may occur.

Peritonsillar abscess (quinsy) develops between the capsule of the tonsil and the muscular bed of its fossa, being usually situated above and lateral to the tonsil. Such abscesses should be opened immediately and the cavity subjected to hot mouth washes while the patient is placed under standard antibiotic therapy.

Lung abscesses are among the more serious types. With the advent of antibiotics, the occurrence and severity of lung abscesses decreased markedly. Over half of the lung abscesses seen originate from a necrotizing suppurative bronchopneumonia resulting from the aspiration of mixed bacteria from the mouth and throat. Lung abscesses are sometimes associated with periodontal disease. In most cases, mixed anaerobic bacteria, such as *Fusobacterium nucleatum*, *Bacteroides melaninogenicus*, and anaerobic or microaerophilic streptococci and *Peptostreptoccus* predominate. *B. Fragilis* also may be present. Abscess formation is uncommon in pneumococcal pneumonia. Lung abscesses also may result from tumors or foreign bodies that cause bronchial obstruction. Other possible causes include pulmonary tuberculosis, fungal infection, and actinomycosis. Cough is present in nearly all patients. Copious foul sputum may result from drainage of the abscess into the bronchial tree. Chest pain and fever are common symptoms. X-rays may be required to confirm the presence of a lung abscess. Sputum examination is critical to diagnosis. Bronchoscopy is usually reserved for more difficult cases. Intravenous penicillin followed by oral penicillin V may be indicated. For penicillin-allergic patients, clindamycin may be used. Adequate drainage is also an important element of therapy. Where empyema is a complication of lung abscess, external drainage is required. Surgery is required in only a minimum of cases of lung abscesses, but was frequently required prior to antibiotics.

Liver abscess is most commonly caused by an amoeba (*Entameba histolytica*) which reaches the liver via the portal vein from sites where trophozoites have penetrated the colonic epithelium and the vessels of the submucosa. The abscess contents are not classically pus because they do not contain inflammatory cells and bacterial residues; the contents are usually sterile and contain only lysed liver cells. The infection is present worldwide, but is most common in tropical areas where crowded living conditions and poor sanitation exist. Africa, Latin America, Southeast Asia, and India have significant health problems associated with this disease. Transmission occurs through ingestion of cysts in fecally contaminated food or water, use of human excrement as fertilizer, and person-to-person contact. Symptoms that occur are fever, abdominal pain in the right hypochondrium, epigastrium, and right shoulder, continuous stabbing with general discomfort, uneasiness, or ill feeling (malaise), sweating, chills, loss of appetite, weight loss, diarrhea, jaundice, joint pain (may occur), a Metronidazole is the drug of first choice in treatment together with aspiration of the abscess contents, although in small abscesses the chemotherapy may suffice.

Intra-abdominal abscesses usually contain multiple bacterial species. Anaerobic bacteria are present in 60–70% of cases because of the proximity of the peritoneum to the bowel. The abscesses range from a small, acute disorder to a chronic process that causes intermittent fever, weight loss, and anemia. These "smouldering" abscesses sometimes result

from a prior infection that was not fully eradicated by antibiotic therapy, allowing a pocket of infection to persist and slowly develop. Physicians, when attempting to diagnose a fever of undetermined origin, will usually ask the patient if there has been relatively recent abdominal surgery. The principal treatment for subphrenic abscesses is surgical drainage. Multiple antibiotic therapy is also used to reach a spectrum of possible causative organisms.

Although appendicitis is not classically considered an abscess, its treatment follows the general approach since delay in treatment can lead to generalized peritonitis or development of an abscess in the appendicular region.

Mediastinitis is an inflammation of the wall dividing the two pleural cavities; a common complication is mediastinal abscess. Sometimes the abscess opens and empties its contents into the trachea; either the patient will cough up large amounts of pus, or he may suffocate. Mediastinitis may occur as a result of perforation of the esophagus. This can happen when a sharp foreign body becomes lodged in the esophagus, during attempts to remove it, or during examination of the organ for other reasons. Mediastinitis also can result from a bullet or stab wound.

Abscess of the breast may occur within the first month after childbirth. It is caused by infections entering through a "cracked nipple." The unfortunate consequences of a breast abscess are that the infant is deprived of breast milk, plus the fact that the mother has a long period of discomfort and pain. Treatment is instituted as quickly as possible in order to avoid a prolonged convalescent period, as well as the possibility of the destruction of a large amount of breast tissue.

Anal infections may cause anal fissure, hemorrhoids, abscess, and fistula, and are usually the result of invasion of the numerous tiny glands or crypts, which abound in the tissues adjacent to the anus. If the infection spreads through the wall of the anus, an abscess may occur in the tissues around the anus, and this may burst through the skin around the anus or back into the rectum. In either case, the abscess cavity has two openings, the original site of entry of the infection and the point where it bursts through. Fistula is the term by which such a condition is designated.

In *abscess of the external ear*, there is pain and tenderness over the affected area. The auricle may enlarge to two or three times the normal size. If proper care is not given, the ear may be permanently distorted in shape. Antibiotics and sulfonamide drugs may be used effectively. Surgical treatment may be required, but only after careful examination by a specialist.

Intracranial abscesses are usually derived from middle ear infections, which account for two-thirds of the cases, while frontal sinus infections account for a further one-sixth. The infection is blood-borne after clinical septicemia and may follow tooth extraction. Although the infection may initially be entirely extra-dural, it will eventually penetrate the dura, causing a variety of problems — even ventriculitis. Cranial abscesses are usually surrounded by a considerable volume of edematous brain tissue and the mass effect of the edema can equal or exceed the potential damage of the abscess mass itself.

Epidural abscesses of the spinal cord are usually the result of *Staphylococcus* infections and are usually metastatic from other sites. They can, however, lead to a rapidly advancing paraplegia, and in such cases only myelography can distinguish the conditions. Treatment requires prompt evacuation and antibiotic therapy, but even then prognosis is not good because permanent damage may result to the spinal cord.

Cutaneous abscesses a collection of pus and infected material in or on the skin. Skin abscesses are fairly common. They are caused when a localized infection causes pus and infected material to collect in the skin or subcutaneous tissue.

Skin abscesses may follow a bacterial infection, commonly an infection with staphylococcus (staph aureus is most common). They can develop after a minor wound, injury, or as a complication of folliculitis or boils (furuncles, carbuncles). Skin abscesses may occur anywhere on the body. They affect people of all ages.

The abscess can obstruct and impinge on the functioning of deeper tissues. The infection may spread locally or systemically. The spread of infection through the bloodstream may cause severe complications. Most skin abscesses are curable with treatment.

Periapical abscesses occur at the apical (apex) region of a tooth as the result of death of the pulp tissue. Periodontal abscesses occur in the tissues closely surrounding a tooth, such as gingiva, bone, or the periodontal membrane. When an abscess breaks through a limiting membrane, working through surrounding bone to external soft tissue, a gum-boil may result.

Blanton/Dade City, FL

ABSCISSION. This term is applied to the process whereby leaves, leaflets, fruits, or other plant parts become detached from the plant. Leaf abscission is a characteristic phenomenon of many species of woody dicots and is especially conspicuous during the autumn period of leaf fall. The onset of abscission seems to be regulated by plant hormones. Three main stages can be distinguished in the usual process of leaf abscission. The first is the formation of an abscission layer that is typically a transverse zone of parenchymatous cells located at the base of the petiole. The cells of this layer may become differentiated weeks or even months before abscission actually occurs. The second step is the abscission process proper that occurs as a result of a dissolution of the middle lamellae of the cells of the abscission layer. This results in the leaf remaining attached to the stem only by the vascular elements which are soon broken by the pressure of wind or the pull of gravity and the leaf falls from the plant. In the final stage of the process the exposed cells of the leaf scar are rendered impervious to water by lignification and suberization of the walls.

Subsequently other layers of corky cells develop beneath the outer layer. These layers eventually become a part of the periderm of the stem. The broken xylem elements of the leaf scar become plugged with gums or tyloses and the phloem elements become compressed and sealed off.

In some kinds of plants an abscission layer is only imperfectly formed and in many others, especially herbaceous species, no abscission layer develops at the base of the petiole. In a few herbaceous species, of which coleus, begonia, and fuchsia are examples, an abscission layer develops. In the majority of herbaceous species, however, and in some woody species, there is no true abscission process. In such herbaceous plants most or all of the leaves are retained until the death of the plant. In the woody plants falling in this category (example: shingle oak, *Quercus imbricaria*) the leaves are shed only by mechanical disruption from the plant. Abscission of the fruits of apple and doubtless of many other species occurs in much the same manner as abscission of leaves. The abscission of apple fruits can be artificially retarded by spraying them with certain growth regulators.

Various plant hormones and plant growth regulators can be of help to the fruit producer in terms of controlling the timing of abscission. See also **Gibberellic Acid and Gibberellin Plant Growth Hormones**; and **Plant Growth Modification and Regulation**. See also related entries under **Tree**.

Abscission is covered in detail in "Abscission," by F.T. Addicott, University of California Press, Berkeley, California, 1982.

ABSOLUTE. 1. Pertaining to a measurement relative to a universal constant or natural datum, as absolute coordinate system, absolute altitude, absolute temperature.

2. Complete, as in absolute vacuum.

ABSOLUTE ALTIMETER. An instrument intended to give acceptably accurate, direct indications of absolute altitude.

ABSOLUTE ALTITUDE. Altitude above the actual surface, either land or water, of a planet or natural satellite.

ABSOLUTE ANGULAR MOMENTUM. The angular momentum as measured in an absolute coordinate system; hence, the vector product of the position vector of a particle into the absolute momentum of the particle.

In the atmosphere the absolute angular momentum M per unit mass of air is equal to the sum of the angular momentum relative to the earth and the angular momentum due to the rotation of the earth:

$$M = ur\cos\phi + \Omega r^2\cos^2\phi,$$

where r is the distance from the center of the earth to the particle, u the relative eastward component of velocity, φ the latitude, and Ω the angular rotation rate of the earth. Since the earth's atmosphere is shallow, the variable r is often replaced by the constant a, defined as the radius of the earth. The absolute angular momentum per unit mass is then approximated by

$$M = ua\cos\phi + \Omega a^2\cos^2\phi.$$

See also **Angular Momentum**.

AMS

ABSOLUTE CAVITY RADIOMETER. A combined electrical substitution and cavity radiometer where the electrical substitution inequivalence, efficiency of the cavity, the area of the entrance aperture, radiative and conductive losses, and other energy exchanges are accounted for such that the electrically substituted heating can be absolutely equated to the radiant heating of the detector.

Most currently existing absolute cavity radiometers are designed for the measurement of direct solar irradiance. The World Radiation Reference (WRR) scale for solar irradiance observations used in many meteorological and climatological applications is defined by a group of well-characterized absolute cavity radiometers maintained by the World Radiation Center (WRC), http://www.pmodwrc.ch/, in Davos, Switzerland.

AMS

ABSOLUTE COORDINATE SYSTEM. An inertial coordinate system that is fixed with respect to the stars. In theory, no absolute coordinate system can be established because the reference stars are themselves in motion. In practice, such a system can be established to meet the demands of the problem concerned by the selection of appropriate reference stars.

ABSOLUTE DELAY. 1. The time interval between the transmission of sequential signals. Also called *delay*.

2. Specifically, in loran, the time interval between transmission of a signal from the A-station and transmission of the next signal from the B-station.

ABSOLUTE HUMIDITY. The amount of water vapor actually present in unit quantity of a gas, generally expressed as mass of water vapor per unit volume of gas + water vapor, e.g., as grains per cubic foot.

ABSOLUTE INSTABILITY. 1. The state of a column of air in the atmosphere when it has a superadiabatic lapse rate of temperature (i.e., greater than the dry-adiabatic lapse rate). An air parcel displaced vertically would be accelerated in the direction of the displacement. The kinetic energy of the parcel would consequently increase with increasing distance from its level of origin. *See* parcel method, conditional instability, absolute stability. 2. (Also called *mechanical instability*.) The state of a column of air in the atmosphere when its lapse rate of temperature is greater than the autoconvective lapse rate. In such a column the air density would increase with elevation.

See also **Autoconvection**.

AMS

ABSOLUTE MAGNITUDE (symbol M). In astronomy, "absolute magnitude" is the apparent magnitude, m, an object would have if it were at a standard luminosity distance away from us. It allows the overall brightnesses of objects to be compared without regard to distance.

The absolute magnitude uses the same convention as the visual magnitude, with a ~ 2.512 difference in brightness between step rates (because $2.512^5 \approx 100$). The Milky Way, for example, has an absolute magnitude of about -20.5. So a quasar at an absolute magnitude of -25.5 is 100 times brighter than our galaxy. If this particular quasar and our galaxy could be seen side by side at the same distance, the quasar would be 5 magnitudes (or 100 times) brighter than our galaxy.

Absolute Magnitude for Stars and Galaxies (M)

In stellar and galactic astronomy, the standard distance is 10 parsecs (about 32.616 light years, or 3×10^{14} km) from Earth. A star at ten parsecs has a parallax of 0.1† (100 milli arc seconds).

In defining absolute magnitude it is necessary to specify the type of electromagnetic radiation being measured. When referring to total energy output, the proper term is "bolometric magnitude." The dimmer an object (at a distance of 10 parsecs) would appear, the higher its absolute magnitude. The lower an object's absolute magnitude, the higher its luminosity. A mathematical equation relates apparent magnitude with absolute magnitude, via parallax.

Many stars visible to the naked eye have an absolute magnitude which is capable of casting shadows from a distance of 10 parsecs; Rigel (-7.0), Deneb (-7.2), Naos (-7.3), and Betelgeuse (-5.6).

For comparison, Sirius has an absolute magnitude of 1.43 and the Sun has an absolute visual magnitude of 4.83 (it actually serves as a reference point). Absolute magnitudes for stars generally range from -10 to $+17$. The absolute magnitude for galaxies can be much lower (brighter). For example, the giant elliptical galaxy M87 has an absolute magnitude of -22.

You can compute the absolute magnitude M of a star given its apparent magnitude m and luminosity distance D_L:

$$M = m - 5(\log_{10} D_L - 1)$$

where D_L is the stars luminosity distance in parsecs, which are ($\approx$3.2616 light-years).

For nearby astronomical objects (such as stars in our galaxy) the luminosity distance D_L is almost identical to the real distance to the object, because spacetime within our galaxy is almost Euclidean. For much more distant objects the Euclidean approximation is not valid, and General Relativity must be taken into account when calculating the luminosity distance of an object.

In the Euclidean approximation for nearby objects, the absolute magnitude M of a star can be calculated from its apparent magnitude and parallax:

$$M = m + 5(\log_{10} \pi + 1)$$

where is the star's parallax in seconds of an arc.

Examples:
Rigel has a visual magnitude of $m_V = 0.18$ and distance about 773 light-years.

$$M_V \text{ Rigel} = 0.18 + 5^* \log_{10}(32.616/773) = -6.7$$

Vega has a parallax of $0.133'$, and an apparent magnitude of $+0.03$

$$M_V \text{ Vega} = 0.03 + 5^*(1 + \log_{10}(0.133)) = +0.65$$

Alpha Centauri has a parallax of $0.750'$ and an apparent magnitude of -0.01

$$M_V \ \alpha \text{ Cen} = -0.01 + 5^*(1 + \log_{10}(0.750)) = +4.37$$

Apparent Magnitude. Given the absolute magnitude M, for objects within our galaxy you can also calculate the apparent magnitude m from any distance d:

$$m = M + 5(\log_{10} d - 1)$$

For objects at very great distances (outside our galaxy) the luminosity distance D_L must be used instead of d. See also **Apparent Magnitude**.

Absolute Magnitude for Planets (H)

For planets, comets and asteroids a different definition of absolute magnitude is used which is more meaningful for nonstellar objects.

In this case, the absolute magnitude is defined as the apparent magnitude that the object would have if it were one astronomical unit (au) from both the Sun and the Earth and at a phase angle of zero degrees. This is a physical impossibility, but it is convenient for purposes of calculation.

To convert a stellar or galactic absolute magnitude into a planetary one, subtract 31.57. This factor also corresponds to the difference between the Sun's visual magnitude of -26.8 and its (stellar) absolute magnitude of $+4.8$. Thus, the Milky Way (galactic absolute magnitude -20.5) would have a planetary absolute magnitude of -52.

Formula for H: (Absolute Magnitude)

$$H = m_{\text{Sun}} - 5\log_{10} \frac{\sqrt{a}r}{d_0}$$

where m_{Sun} is the apparent magnitude of the Sun at 1 au (-26.73), a is the geometric albedo of the body (a number between 0 and 1), r is its radius and d_0 is 1 au ($\approx$149.6 Gm).

Example:
Moon: $a_{\text{Moon}} = 0.12$, $r_{\text{Moon}} = 3476/2$ km $= 1738$ km

$$H_{\text{Moon}} = m_{\text{Sun}} - 5\log_{10} \frac{\sqrt{a_{\text{Moon}}}r_{\text{Moon}}}{d_0} = +0.25$$

Apparent Magnitude. The absolute magnitude can be used to help calculate the apparent magnitude of a body under different conditions.

$$m = H + 2.5\log_{10}\left(\frac{d_{BS}^2 d_{BO}^2}{p(\chi)d_0^4}\right)$$

where d_0 is 1 au, χ is the phase angle, the angle between the Sun-Body and Body-Observer lines; by the law of cosines:

$$cos\chi = \frac{d_{BO}^2 + d_{BS}^2 - d_{OS}^2}{2d_{BO}d_{BS}}$$

$p(\chi)$ is the phase integral (integration of reflected light; a number in the 0 to 1 range)

Example:
(An ideal diffuse reflecting sphere) − A reasonable first approximation for planetary bodies

$$p(\chi) = \frac{2}{3}((1 - \frac{\chi}{\pi})\cos\chi + (1/\pi)\sin\chi)$$

A full-phase diffuse sphere reflects 2/3 as much light as a diffuse disc of the same diameter;

Distances:

d_{BO} is the distance between the observer and the body
d_{BS} is the distance between the Sun and the body
d_{OS} is the distance between the observer and the Sun

Examples:
Moon

$$H_{\text{Moon}} = +0.25$$

$$d_{OS} = d_{BS} = 1 \text{ au}$$

$$d_{BO} = 384.5 \text{ Mm} = 2.57 \text{ mau}$$

How bright is the Moon from Earth?
Full Moon:$\chi = 0$, $(p(\chi) \approx 2/3)$

$$m_{\text{Moon}} = 0.25 + 2.5\log_{10}\left(\frac{3}{2}0.00257^2\right) = -12.26$$

(Actual −12.7) A full Moon reflects 30% more light at full phase than a perfect diffuse reflector predicts.

Quarter Moon: $\chi = 90^\circ$, $p(\chi) \approx \frac{2}{3\pi}$ (if diffuse reflector)

$$m_{\text{Moon}} = 0.25 + 2.5\log_{10}\left(\frac{3\pi}{2}0.00257^2\right) = -11.02$$

(Actual approximately −11.0) The diffuse reflector formula does better for smaller phases.

See also **Star**; and **Stellar Magnitude**.

ABSOLUTE MANOMETER. 1. A gas manometer whose calibration, which is the same for all ideal gases, can be calculated from the measurable physical constants of the instrument.

2. A manometer that measures absolute pressure.

ABSOLUTE MOTION. Motion relative to a fixed point. See also **Absolute Coordinate System**.

ABSOLUTE PRESSURE. 1. In engineering literature, a term used to indicate pressure above the absolute zero value of pressure that theoretically obtains in empty space or at the absolute zero of temperature as distinguished from gage pressure.

2. In high-vacuum technology, pressure is understood to correspond to absolute pressure, not gage pressure, and therefore the term absolute pressure is rarely used. See also **Pressure**.

ABSOLUTE RADIATION SCALE (ARS). Also referred to as the World Radiation Reference (WRR). A radiation scale for measurement of solar exitance (irradiance). Prior to 1956, the Ångström Scale (ÅS) (1905) and Smithsonian Scale (SS) (1913) were used. Each scale was calibrated against a different radiation detector (i.e., the Ångström compensation pyrheliometer and water-stirred pyrheliometer, respectively), and yielded slightly different values for the irradiance, with the ÅS reading roughly 3.5% lower than the SS. The International Pyrheliometric Scale (IPS), defined in 1956, represented a numerical compromise between these two scales. In 1975, the IPS was replaced by the Absolute Radiation Scale (ARS). The ARS is calibrated against six absolute cavity radiometers maintained at the World Radiation Center in Davos, Switzerland. The variation among the six radiometers is about 0.3%. The IPS was found to give measured irradiance levels that were about 2%−3% percent lower than the more precise ARS. See also **Pyrheliometer**.

AMS

ABSOLUTE SPACE-TIME. A fundamental concept underlying Newtonian mechanics is that there exists a preferred reference system to which all measurements should be referred. This is known as absolute space-time. The assumption of such a system is replaced in relativistic mechanics by the principle of equivalence. See **Equivalence Principle**; and **Relativity and Relativity Theory**.

ABSOLUTE SYSTEM OF UNITS. 1. A system of units in which a small number of units are chosen as fundamental, and all other units are derived from them.

2. Specifically, a system of electrical units put into effect by international agreement on January 1, 1948. Prior to January 1, 1948 the international system was in effect; the two systems can be converted by the following relationships:

$$1 \text{ mean international ohm} = 1.00049 \text{ absolute ohm}$$

$$1 \text{ mean international volt} = 1.00034 \text{ absolute volt.}$$

"Electric units, called *international*, for current and resistance had been introduced by the International Electrical Congress held in Chicago in 1893, and the definitions of the "international" ampere and the "international" ohm were confirmed by the International Conference of London in 1908.

Although, it was already obvious, on the occasion of the 8th CGPM (1933) that there was a unanimous desire to replace those "international" units by so-called "absolute" units, the official decision to abolish them was only taken by the 9th CGPM (1948), which adopted for the unit of electric current, the "ampere".

The previous is an excerpt from WWW version of the National Institute of Standards and Technology: Physics Laboratory's International System of Units (SI). See also **Units and Standards**.

ABSOLUTE TEMPERATURE. The fundamental temperature scale used in theoretical physics and chemistry, and in certain engineering calculations such as the change in volume of a gas with temperature. Absolute temperatures are expressed either in degrees Kelvin or in degrees Rankine, corresponding respectively to the centigrade and Fahrenheit scales. Temperatures in Kelvins are obtained by adding 273 to the centigrade temperature (if above °C) or subtracting the centigrade temperature from 273 (if below °C). Degrees Rankine are obtained by subtracting 460 from the Fahrenheit temperature.

ABSOLUTE VACUUM. A void completely empty of matter. Also called perfect vacuum. An absolute vacuum is not obtainable.

ABSOLUTE ZERO. Conceptually that temperature where there is no molecular motion, no heat. On the Celsius scale, absolute zero is −273.15 °C, on the Fahrenheit scale, −459.67 °F; and zero Kelvin (0 K). The concept of absolute zero stems from thermodynamic postulations.

Heat and temperature were poorly understood prior to Carnot's analysis of heat engines in 1824. The Carnot cycle became the conceptual foundation for the definition of temperature. This led to the somewhat later work of Lord Kelvin, who proposed the Kelvin scale based upon a consideration of the second law of thermodynamics. This leads to a temperature at which all the thermal motion of the atoms stops. By using this as the zero point or absolute zero and another reference point to determine the size of the degrees, a scale can be defined. The Comité Consultative of the International Committee of Weights and Measures selected 273.16 K as the value for the triple point for water. This set the ice-point at 273.15 K.

From the standpoint of thermodynamics, the thermal efficiency E of an engine is equal to the work W derived from the engine divided by the heat supplied to the engine, $Q2$. If $Q1$ is the heat exhausted from the engine,

$$E = (W/Q2) = (Q2 - Q1)/Q2 = 1 - (Q1/Q2)$$

where W, $Q1$, and $Q2$ are all in the same units. A Carnot engine is a theoretical one in which all the heat is supplied at a single high temperature

and the heat output is rejected at a single temperature. The cycle consists of two adiabatics and two isothermals. Here the ratio $Q1/Q2$ must depend only on the two temperatures and on nothing else. The Kelvin temperatures are then defined by the relation where $Q1/Q2$ is the ratio of the heats rejected and absorbed, and $T1/T2$ is the ratio of the Kelvin temperatures of the reservoir and the source. If one starts with a given size for the degree, then the equation completely defines a thermodynamic temperature scale.

$$\frac{Q1}{Q2} = \frac{T1}{T2}$$

A series of Carnot engines can be postulated so that the first engine absorbs heat Q from a source, does work W, and rejects a smaller amount of heat at a lower temperature. The second engine absorbs all the heat rejected by the first one, does work, and rejects a still smaller amount of heat which is absorbed by a third engine, and so on. The temperature at which each successive engine rejects its heat becomes smaller and smaller, and in the limit this becomes zero so that an engine is reached which rejects no heat at a temperature that is absolute zero. A reservoir at absolute zero cannot have heat rejected to it by a Carnot engine operating between a higher temperature reservoir and the one at absolute zero. This can be used as the definition of absolute zero. Absolute zero is then such a temperature that a reservoir at that temperature cannot have heat rejected to it by a Carnot engine which uses a heat source at some higher temperature.

ABSORBANCE. By combining the laws of Bouguer and Beer, the absorbance

$$A = -\log T = \log \frac{I_0}{I} = abc$$

where T is the transmittance, I_0 and I are the intensities of light incident and transmitted by a sample of thickness, b, concentration c (if the sample is in solution) and absorptivity a. It is assumed that all necessary corrections have been made in a reported value of A, hence terms such as absorbancy, absorptance, and absorptancy should not be used.

ABSORBER. In general, a medium, substance or functional part that takes up matter or energy. In radiation and particle physics, an absorber is a body of material introduced between a source of radiation and a detector to (1) determine the energy or nature of the radiation; (2) to shield the detector from the radiation; or (3) to transmit selectively one or more components of the radiation, so that the radiation undergoes a change in its energy spectrum. Such an absorber may function through a combination of processes of true absorption, scattering and slowing-down.

ABSORPTIMETRY. A method of instrumental analysis, frequently chemical, in which the absorption (or absence thereof) of selected electromagnetic radiation is a qualitative (and often quantitative) indication of the chemical composition of other characteristics of the material under observation. The type of radiation utilized in various absorption-type instruments ranges from radio and microwaves through infrared, visible, and ultraviolet radiation to x-rays and gamma rays. See also **Analysis (Chemical)**; and **Spectro Instruments**.

ABSORPTION BAND. A range of wavelengths (or frequencies) in the electromagnetic spectrum within which radiant energy is absorbed by a substance. When the absorbing substance is a polyatomic gas, an absorption band actually is composed of a group of discrete absorption lines, which appear to overlap. Each line is associated with a particular mode of vibration or rotation induced in a gas molecule by the incident radiation. The absorption bands of oxygen and ozone are often referred to in the literature of atmospheric physics.

The important bands for oxygen are (1) the Hopfield bands, very strong, between about 670 and 1000 angstroms in the ultraviolet; (2) a diffuse system between 1019 and 1300 angstroms; (3) the Schumann-Runge continuum, very strong, between 1350 and 1760 angstroms; (4) the Schumann-Runge bands between 1760 and 1926 angstroms; (5) the Herzberg bands between 2400 and 2600 angstroms; (6) the atmospheric bands between 5380 and 7710 angstroms in the visible spectrum; and (7) a system in the infrared at about 1 micron.

The important bands for ozone are the Hartley bands between 2000 and 3000 angstroms in the ultraviolet, with a very intense maximum absorption at 2550 angstroms; the Huggins bands, weak absorption between 3200 and 3600 angstroms; the Chappius bands, a weak diffuse system between 4500 and 6500 angstroms in the visible spectrum; and the infrared bands centered at 4.7, 9.6 and 14.1 microns, the latter being the most intense.

See also **Absorption Spectrum**; **Electromagnetic Phenomena**; and **Electromagnetic Spectrum**.

ABSORPTION COEFFICIENT. 1. For the absorption of one substance or phase in another, as in the absorption of a gas in a liquid, the absorption coefficient is the volume of gas dissolved by a specified volume of solvent; thus a widely used coefficient is the quantity a in the expression $\alpha = V_0/V_p$, where V_0 is the volume of gas reduced to standard conditions, V is the volume of liquid, and p is the partial pressure of the gas.

2. In the case of sound, the absorption coefficient (which is also called the acoustical absorptivity) is defined as the fraction of the incident sound energy absorbed by a surface or medium, the surface being considered part of an infinite area.

3. In the most general use of the term, absorption coefficient, applied to electromagnetic radiation and atomic and subatomic particles, is a measure of the rate of decrease in intensity of a beam of photons or particles in its passage through a particular substance. One complication in the statement of the absorption coefficient arises from the cause of the decrease in intensity. When light, x-rays, or other electromagnetic radiation enters a body of matter, it experiences in general two types of attenuation. Part of it is subjected to scattering, being reflected in all directions, while another portion is absorbed by being converted into other forms of energy. The scattered radiation may still be effective in the same ways as the original, but the absorbed portion ceases to exist as radiation or is re-emitted as secondary radiation. Strictly, therefore, we have to distinguish the true absorption coefficient from the scattering coefficient; but for practical purposes it is sometimes convenient to add them together as the total attenuation or extinction coefficient.

If appropriate corrections are made for scattering and related effects, the ratio I/I_0 is given by the laws of Bouguer and Beer. Here, I_0 is the intensity or radiant power of the light incident on the sample and I is the intensity of the transmitted light. This ratio $I/I_0 = T$ is known as the transmittance. See also **Spectrochemical Analysis (Visible)**.

ABSORPTION CURVE. The graphical relationship between thickness of absorbing material or concentration of dissolved substance and intensity of transmitted radiation.

ABSORPTION DISCONTINUITY. A discontinuity appearing in the absorption coefficient of a substance for a particular type of radiation when expressed as a function of the energy (or frequency or wavelength) of this radiation. An absorption discontinuity is often associated with anomalies in other variables such as the refractive index. See **Anomalous Dispersion**.

ABSORPTION EDGE. The wavelength corresponding to an abrupt discontinuity in the intensity of an absorption spectrum, notably an x-ray absorption spectrum, which gives the appearance of a sharp edge in the display of such a spectrum.

ABSORPTION (Energy). The process whereby the total number of particles emerging from a body of matter is reduced relative to the number entering as a result of interaction of the particles with the body. Also, the process whereby the kinetic energy of a particle is reduced while traversing a body of matter. This loss of kinetic energy or radiation is also referred to as moderation, slowing, or stopping. See also **Black Body**. The absorption of mechanical energy by dynamometers, which convert the mechanical energy to heat or electricity, has led to the use of the term "absorption dynamometer" to distinguish these machines. See also **Dynamometer**. In acoustics, absorption is the process whereby some or all of the energy of sound waves is transferred to a substance on which they are incident or which they traverse.

ABSORPTION (Physiology). The process by which materials enter the living substance of which the organism is composed. Materials including food and oxygen are taken into special organs by ingestion and respiration, but they must pass through the cell wall to become an integral part of the organism by absorption. The basic physical forces involved are those of osmosis and diffusion.

ABSORPTION (Process). Absorption is commonly used in the process industries for separating materials, notably a specific gas from a mixture of gases; and in the production of solutions such as hydrochloric and sulfuric acids. Absorption operations are very important to many air pollution abatement systems where it is desired to remove a noxious gas, such as sulfur dioxide or hydrogen sulfide, from an effluent gas prior to releasing the material to the atmosphere. The absorption medium is a liquid in which (1) the gas to be removed, i.e., absorbed is soluble in the liquid, or (2) a chemical reaction takes place between the gas and the absorbing liquid. In some instances a chemical reagent is added to the absorbing liquid to increase the ability of the solvent to absorb.

Wherever possible, it is desired to select an absorbing liquid that can be regenerated and thus recycled and used over and over. An example of absorption with chemical reaction is the absorption of carbon dioxide from a flue gas with aqueous sodium hydroxide. In this reaction, sodium carbonate is formed. This reaction is irreversible. However, continued absorption of the carbon dioxide with the sodium carbonate solution results in the formation of sodium acid carbonate. The latter can be decomposed upon heating to carbon dioxide, water, and sodium carbonate and thus the sodium carbonate can be recycled.

Types of equipment used for absorption include (1) a packed tower filled with packing material, absorbent liquid flowing down through the packing (designed to provide a maximum of contact surface), and gas flowing upward in a countercurrent fashion; (2) a spray tower in which the absorbing liquid is sprayed into essentially an empty tower with the gas flowing upward; (3) a tray tower containing bubble caps, sieve trays, or valve trays; (4) a falling-film absorber or wetted-wall column; and (5) stirred vessels. Packed towers are the most commonly used.

A representative packed-type absorption tower is shown in Fig. 1. In addition to absorption efficiency, a primary concern of the tower designer is that of minimizing the pressure drop through the tower. The principal elements of pressure drop are shown at the right of the diagram. Important to efficiency of absorption and pressure drop is the type of packing used. As shown by Fig. 2, over the years numerous types of packing (mostly ceramic) have been developed to meet a wide variety of operating parameters. A major objective is that of providing as much contact surface as is possible with a minimum of pressure drop. Where corrosion conditions permit, metal packing sometimes can be used. Of the packing designs illustrated, the berl saddles range in size from $\frac{1}{4}$ inch (6 millimeters) up to 2 inches (5 centimeters); raschig rings range from $\frac{1}{4}$ inch (6 millimeters) up to 4 inches (10 centimeters); lessing rings range from 1 inch (2.5 centimeters) up to 2 inches (5 centimeters); partition and spiral rings range from 3 inches (7.5 centimeters) up to 6 inches (15 centimeters).

In operation, the absorbing liquid is pumped into the top of the column where it is distributed by means of a weir to provide uniform distribution

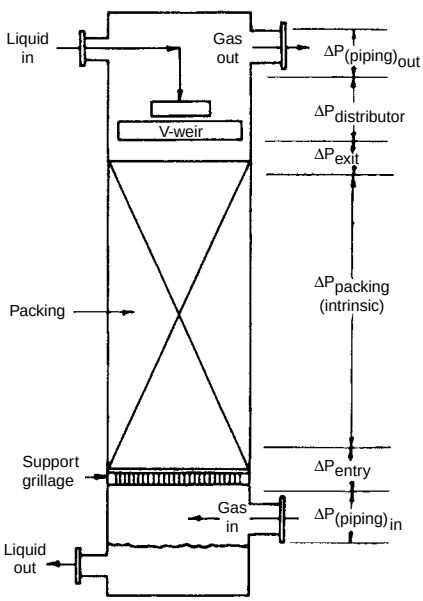

Fig. 1. Section of representative packed absorption tower.

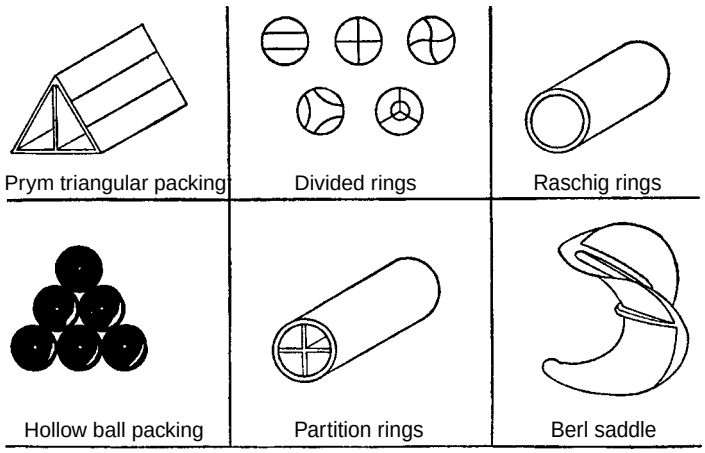

Fig. 2. Types of packing used in absorption towers.

of the liquid over the underlying packing. Gas enters at the base of the tower and flows upward (countercurrent with the liquid) and out the top of the tower. The liquid may or may not be recycled without regeneration, depending upon the strength of the absorbent versus the quantity of material (concentration) in the gas to be removed. In a continuous operation, of course, a point is reached where fresh absorbing liquid must be added.

It is interesting to note that over 100,000 of the $\frac{1}{4}$-inch (6-millimeter) size packing shapes will be contained in each cubic foot (0.02832 cubic meter) of tower space if dense packing is desired.

In the purification of natural gas, the gas is fed into the bottom of an absorption tower where the gas is contacted counter currently by a lean absorption oil. Hydrochloric acid is produced by absorbing gaseous hydrogen chloride in water, usually in a spray-type tower. Unreacted ammonia in the manufacture of hydrogen cyanide is absorbed in dilute sulfuric acid. In the production of nitric acid, ammonia is catalytically oxidized and the gaseous products are absorbed in water. The ethanolamines are widely used in scrubbing gases for removal of acid compounds. Hydrocarbon gases containing hydrogen sulfide can be scrubbed with monoethanolamine, which combines with it by salt formation and effectively removes it from the gas stream. In plants synthesizing ammonia, hydrogen and carbon dioxide are formed. The hydrogen can be obtained by counter currently scrubbing the gas mixture in a packed or tray column with monoethanolamine which absorbs the carbon dioxide. The latter can be recovered by heating the monoethanolamine. In a nonliquid system, sulfur dioxide can be absorbed by dry cupric oxide on activated alumina, thus avoiding the disadvantages of a wet process. Sulfuric acid is produced by absorbing sulfur trioxide in weak acid or water.

See also **Coal**; **Ethanolamines**; **Chromatography**; and **Pollution (Air)**.

ABSORPTION SPECTROSCOPY. An important technique of instrumental analysis involving measurement of the absorption of radiant energy by a substance as a function of the energy incident upon it. Adsorption processes occur throughout the electromagnetic spectrum, ranging from the *Y* region (nuclear resonance absorption of the Mossbauer effect) to the radio region (nuclear magnetic resonance). In practice, they are limited to those processes that are followed by the emission of radiant energy of greater intensity than that which was absorbed. The absorption process, involve absorption of a photon by the substance being analyzed. If it loses the excess energy by emitting a photon of less energy than that absorbed, fluorescence or phosphorescence is said to occur, depending on the lifetime of the excited state.

The emitted energy is normally studied. If the source of radiant energy and the absorbing species are in identical energy states (in resonance), the excess energy is often given up by the nondirectional emission of a photon whose energy is identical with the absorbed.

Either adsorption or emission may be studied, depending upon the chemical and instrumental circumstances. If the emitted energy is studied, the term *resonance fluorescence* is often used. However, if the absorbing species releases the excess energy in small steps by intermolecular collision or some other process, it is commonly understood that this phenomenon falls within the realm of absorption spectroscopy. The terms

absorption spectroscopy, *spectrophotometry*, and *absorptimetry* are often used synonymously.

Most absorption spectroscopy is done in the ultraviolet, visible, and infrared regions of the electromagnetic spectrum.

See also **Emission Spectroscopy** and **Infrared Radiation**.

ABSORPTION SPECTRUM. The spectrum of radiation that has been filtered through a material medium. When white light traverses a transparent medium, a certain portion of it is absorbed, the amount varying, in general, progressively with the frequency of which the absorption coefficient is a function. Analysis of the transmitted light may, however, reveal that certain frequency ranges are absorbed to a degree out of all proportion to the adjacent regions; that is, with a distinct selectivity. These abnormally absorbed frequencies constitute, collectively, the "absorption spectrum" of the medium, and appear as dark lines or bands in the otherwise continuous spectrum of the transmitted light. The phenomenon is not confined to the visible range, but may be found to extend throughout the spectrum from the far infrared to the extreme ultraviolet and into the x-ray region.

A study of such spectra shows that the lines or bands therein accurately coincide in frequency with certain lines or bands of the emission spectra of the same substances. This was formerly attributed to resonance of electronic vibrations, but is now more satisfactorily explained by quantum theory on the assumption that those quanta of the incident radiation which are absorbed are able to excite atoms or molecules of the medium to some (but not all) of the energy levels involved in the production of the complete emission spectrum.

A very familiar example is the spectrum of sunlight, which is crossed by innumerable dark lines, the Fraunhofer lines, much has been learned about the constitution of the sun, stars, and other astronomical objects from the Fraunhofer lines.

A noteworthy characteristic of selective absorption is found in the existence of certain anomalies in the refractive index in the neighborhood of absorption frequencies; discussed under Dispersion (Radiation). See also **Absorption Band**; **Electromagnetic Spectrum**; and **Fraunhofer Lines**.

ABSORPTIVITY (Optical). If A is the absorbance of a solution b cm. in thickness and at a concentration c, the absorptivity is $a = A/bc$. See also **Beer's Law**.

ABUNDANCE. The relative amount (% by weight) of a substance in the earth's crust, including the atmosphere and the oceans.

1. The abundance of the elements in the earth's crust is shown in Table 1.
2. The percentages of inorganic compounds in the earth's crust, exclusive of water, are:
    1. SiO_2 55
    2. Al_2O_3 15
    3. $CaCO_3$ 8.8
    4. MgO 1.6
    5. Na_2O 1.6
    6. K_2O 1.9
3. The most abundant organic materials are cellulose and its derivatives, and proteins.

TABLE 1. ABUNDANCE OF THE ELEMENTS IN THE EARTH'S CRUST

Rank	Element	% by wt.
1	Oxygen	49.2
2	Silicon	25.7
3	Aluminum	7.5
4	Iron	4.7
5	Calcium	3.4
6	Sodium	2.6
7	Potassium	2.4
8	Magnesium	1.9
9	Hydrogen	0.9
10	Titanium	0.6
11	Chlorine	0.2
12	Phosphorus	0.1
13	Manganese	0.1
14	Carbon	0.09
15	Sulfur	0.05
16	Barium	0.05
	all others	0.51

Note: In the universe as a whole, the most abundant element is hydrogen.

ABUNDANCE RATIO. The proportions of the various isotopes that make up a particular specimen of an element. See **Chemical Elements**.

ABYSSAL HILLS. Small hills averaging 100–200 meters (330–660 feet) in height that occupy the ocean floor. These may be nearly isolated or may occupy virtually the whole floor. See **Abyssal Plain**.

ABYSSAL PLAIN. An area on the ocean floor having a flat bottom and a very slight slope of less than 1 part in 1000. It is believed that these very flat surfaces arise from the continued deposition of mud and silt from turbidity currents. See **Ocean**. Seismographic studies support that these surfaces consist of such deposits. Mid-ocean canyons may be found on these abyssal plains; these are flat-bottomed depressions in the plains, varying from one to several kilometers (miles) in width and varying in depth up to several hundred meters (feet). These, too, are believed to be the product of certain turbidity currents.

ABYSSAL ROCKS. Proposed by Brögger as a general term for deep-seated igneous rocks, or those that have crystallized from magmas far below the surface of the earth, very slowly and under great pressure. Granite is a typical abyssal rock. The term plutonic is synonymous.

ABYSSAL ZONE. The region of the ocean beyond the point of penetration of light, including the ocean floor in the deep areas. According to various investigators who have descended into the ocean depths, no light penetrates beyond about 1,500 feet (450 meters), and penetration may be much less if the water is murky with suspended particles. The water is always extremely cold in the abyssal zone and the pressure is very great. Still many forms of animal life are to be found at these great depths, feeding upon the organic matter that drifts down from the upper waters.

Abyssal animals fall into two groups: *scavengers*, living on the shower of organic matter, and *predators*, which prey upon the scavengers or upon each other. The most abundant deep-sea animals are the sea cucumbers, snails, crustaceans, tunicates, cephalopods, and fish. The predaceous fish have large mouths filled with long, sharp teeth, and stomachs capable of great stretching; they are actually known to swallow fish larger than themselves. Many of the fish have a lure with a light on the end that attracts prey. Others have rows of light-producing organs on the sides of their bodies. Other animals with light-producing organs are coelenterates, echinoderms, annelids, crustaceans, and cephalopods. It is believed that the lights not only help these animals in finding food, but also in finding each other during the reproductive season. See also **Ecology**; and **Ocean**.

ACACIA TREES. Of the family *Leguminosae* (pea family), the genus *Acacia* represents a large number of mostly evergreen trees and shrubs, particularly abundant in Africa and Australia. The trees like warmth and full sun. The small flowers are aggregated into ball-like or elongate clusters, which are quite conspicuous. The leaves are rather diverse in shape; quite commonly they are dissected into compound pinnate forms; in other

instances, especially in the Australian species, they are reduced even to a point where only the flattened petiole, called a phyllode, remains. This petiole grows with the edges vertical, which some observers consider a protective adaptation against too intense sunlight on the surface. Some species, particularly those growing in Africa and tropical Asia, yield products of commercial value. Gum arabic is obtained from the *Acacia senegal*. A brown or black dye called clutch is obtained from *A. catechu*. Some acacias are used for timber. Shittinwood referred to in the scriptures: "And thou shalt make staves of shittinwood and overlay them with gold," (Exodus 26:26–37), is considered by authorities as wood from *Acacia seyal* (then referred to as the shittah tree).

Certain tropical American species are of particular interest because of the curious pairs of thorns, which are united at their base. These thorns are often hollowed out and used as nests by species of stinging ants. The leaves of some species, notably *Mimosa pudica*, are sensitive to the touch. The mimosa tree or silver wattle, native to Australia, is the *Acacia dealbata*. The leaves are fernlike and of a silver-green coloration. They attain a height of about 50 feet (15 meters) within 20 years, prefer full sun, and can be severely damaged by prolonged frosts. The tree has been introduced into warm regions of other parts of the world and has done well. The so-called catclaw acacia (*A. greggii*) has done well in the southwestern United States. One specimen, selected by American Forests' from its "National Register of Big Trees," is located at Red Rock, New Mexico. The circumference at $4\frac{1}{2}$ feet (1.4 meters) above the base is 6 feet, 5 inches (1.8 meters, 13 centimeters); the height is 49 feet (15 meters); and the spread is 46 feet (14 meters).

The record blackbrush acacia (*A. rigidula*) is found in Arizona. A specimen is also listed in the *American Forests* registry. The circumference at $4\frac{1}{2}$ feet (1.4 meters) above the base is 14 inches (35.6 centimeters); the height is 27 feet (8.23 meters); and the spread is 31 feet (9.45 meters).

The koa acacia (*A. koa* var. hawaiiensis) is found in Hawaii. A specimen is also listed in the *American Forests* registry and is located in the District of Kau. The circumference at $4\frac{1}{2}$ feet (1.4 meters) above the base is 37 feet, 4 inches (11.4 meters); the height is 140 feet (42.7 meters); and the spread is 148 feet (45.1 meters).

A. baileyana, also a native of Australia, is known as the Cootamundra wattle or Bailey's mimosa. It attains a height of 20 feet (6 meters) or more, has long, narrow, waxy evergreen leaves of a silver-green color. The contour of the tree is often weeping.

The *Robinia pseudoacacia*, also referred to as black locust, common acacia, or false acacia, is found in the eastern United States. The tree is highly tolerant of dryness and industrial environments. This tree may attain a height of from 60 to 80 feet (18 to 24 meters), with a trunk diameter up to 4 feet (1.2 meters). It is a highly favored tree for gardens, often described as graceful and decorative.

Under normal environmental conditions, kudus (antelope family) that range freely in certain parts of South Africa (Transvaal) consume the leaves of acacia trees as a regular part of their diet. The leaves contain tannin, an astringent, at all times, but when the trees are under unusual stress, as may be caused by drought or overeating by herbivores, the tannin content of the leaves increases markedly. Even though this results in a very unpleasant taste, the kudus continue to eat the leaves to satiate their appetites during very dry seasons. Excessive consumption of the leaves causes inactivation of liver enzymes of the kudu, resulting in death. Researchers from the University of Pretoria and biologists from Dartmouth College have expanded on this situation, suggesting that other trees, such as sugar maple plants, also produce greater amounts of tannin and other defensive compounds when the leaves are damaged, as by herbivores. Another finding is that affected trees also emit ethylene gas, which can signal trees as far distant as 150 feet (50 meters) to activate the chemical defense process. Laboratory tests indicate that, when these plants are exposed to ethylene, tannin levels are increased in about 30 minutes. Researchers suggest that this may constitute a "natural population regulatory mechanism." Some ranchers who wish to maintain the kudu population now put out alfalfa during extremely dry periods. See also **Allelopathic Substance**.

ACANTHOCEPHALA (Thorny-Headed Worms). Worms, slender and hollow (pseudocoelom) with re-curved hooks on invaginate proboscis, no digestive tracts, and adults parasitic in intestine of vertebrates, with larva in intermediate arthropod host. They are usually regarded as a class of roundworm (*Nematoda*), but ranking as a separate phylum is now favored.

ACANTHUS. Genus of the family *Acanthaceae* (acanthus family). This is a relatively small genus of Mediterranean plants grown mainly for ornamental purposes. The flowers are white or shades of red.

ACARICIDE. A substance, natural or synthetic, used to destroy or control infestations of the animals making up *Arachnida*, *Acarina*, mainly mites and ticks, some forms of which are very injurious to both plants and livestock, including poultry. There are numerous substances that are effective both as acaricides and insecticides; others of a narrower spectrum are strictly acaricides. See also **Insecticide**; and **Insecticide and Pesticide Technology**.

ACARINA. The order of *Arachnida* that includes the mites and ticks.

ACCELERATED FLIGHT (Airplane). When the velocity of an airplane along its flight path contains elements of acceleration, the structure receives increments of inertial or dynamic loading that may prove to be far more severe upon the structure than the loading imposed by the static weight of the airplane and its contents. Consequently, accelerated flight has been the subject of extensive analytical and experimental investigation. Acceleration of rectilinear velocity below the speed of sound, as by increasing the thrust of the power plant in straight level flight, is of small import, since radial accelerations resulting from curvilinear flight at constant speed are so large as to be the critical influence. Cases of curved flight paths capable of accelerations of several g (acceleration due to gravity) are quick pull-ups (or "zooms") from high-speed rectilinear flight, spins, steeply banked turns, and loops. The magnitude of the effect of accelerated flight is well illustrated by considering the centrifugal force on an airplane following a curved flight path in the vertical plane. With a constant tangential speed as low as 120 mph (193 kph), the airplane experiences a radial acceleration of 4 g (4 times the acceleration of gravity) even though the radius of curvature be about 240 feet (73 meters).

ACCELERATION. The rate of change of the velocity with respect to the time is called acceleration. It is expressed mathematically by dv/dt, the vector derivative of the velocity, **v** with respect to the time, t. If the motion is in a straight line whose position is clearly understood, it is convenient to treat the velocity v and the acceleration dv/dt as scalars with appropriate algebraic signs; otherwise they must be treated by vector methods.

Acceleration may be rectilinear or curvilinear, depending upon whether the path of motion is a straight line or a curved line. A body that moves along a curved path has acceleration components at every point. One component is in the direction of the tangent to the curve and is equal to the rate of change of the speed at the point. For uniform circular motion this component is zero. The second component is normal to the tangent and is equal to the square of the tangential speed divided by the radius of curvature at the point. This normal component, which is directed toward the center of curvature, also equals the square of the angular velocity multiplied by the radius of curvature. The acceleration due to gravity is equal to an increase in the velocity of about 32.2 feet (981.5 centimeters)/second/second at the earth's surface and is of prime importance since it is the ratio of the weight to the mass of a body. For examples of acceleration in both curved and linear motion, see **Kinematics**. See also **Angular Velocity and Angular Acceleration**.

ACCELERATION (Due to Gravity). The universal character of the gravitational force for point masses or spherical bodies can be expressed by the equation

$$F = \frac{GM_1M_2}{R^2} \tag{1}$$

where

$M_1, M_2 =$ masses of two bodies
$R =$ distance between two bodies
$G =$ a constant $= 6.670 \times 10^{-8}$ dyne cm^2 gm^{-2}

The constant G is independent of all properties of the particular bodies involved.

TABLE 1. VARIATION OF ACCELERATION DUE TO GRAVITY ON EARTH WITH LATITUDE (AT SEA LEVEL)

Latitude	g centimeters/(second)^2	g feet/(second)^2
0°	977.989	32.0862
10°	978.147	32.0916
20°	978.600	32.1062
30°	979.295	32.1290
40°	980.147	32.1570
50°	981.053	32.1867
60°	981.905	32.2147
70°	982.600	32.2375
80°	983.053	32.2523
90°	983.210	32.2575

The weight of a body of mass M on the earth is the force with which it is attracted to the center of the earth. On the surface of the earth, the weight is given by

$$W = Mg \tag{2}$$

where the acceleration due to gravity is obtained from Equation (1):

$$g = \frac{GM_E}{R_E^2}$$

$$= 980.665 \text{ cm/(second)}^2$$

$$= 32.174 \text{ feet/(second)}^2 (9.81 \text{ meters/(second)}^2) \tag{3}$$

Variation of the acceleration due to gravity at sea level for different latitudes on earth is given in Table 1.

Gravitational force at the surface of the sun, moon, and planets is given in specific entries on these solar system bodies. See also **Gravitation**.

ACCELERATOR. 1. A compound, usually organic, that greatly reduces the time required for vulcanization of natural and synthetic rubbers, at the same time improving the aging and other physical properties. See also **Rubber (Natural)**. Organic accelerators invariably contain nitrogen, and many contain sulfur. The latter type are called *ultra-accelerators* because of their greater activity. The major types include amines, guanidines, thiazoles, thiuram sulfides, and dithiocarbamates. The amines and guanidines are basic, the others acidic. The normal effective concentration of organic accelerators in a rubber mixture is 1% or less depending on the rubber hydrocarbon present. Zinc oxide is required for activation, and in the case of acidic accelerators, stearic acid is required. The introduction of organic accelerators in the early twenties was largely responsible for the successful development of automobile tires and mechanical products for engineering uses. A few inorganic accelerators are still used in low-grade products, e.g., lime, magnesium oxide, and lead oxide. See also **Amines**; and **Guanidine**.

2. A compound added to a photographic developer to increase its activity, such as certain quaternary ammonium compounds and alkaline substances.

3. A particle accelerator.

ACCELERATOR (Particle). See **Particles (Subatomic)**.

ACCELEROMETER. Acceleration is not measured directly, but is computed by measuring the force exerted by restraints that are placed on a mass to hold its position fixed in an accelerating body. The relationship between restraint and acceleration is defined by Newton's second law: $F = ma$ (force equals mass times acceleration). The device used to accomplish the foregoing requirement is known as an *accelerometer*. The accelerometer is the most common type of vibration sensor. See also **Vibration**. The necessary attributes of an accelerometer include small size, light weight, and rugged construction. Both self-generating accelerometers and those requiring electrical excitation are available. The most common is the self-generating piezoelectric device. Typical performance characteristics for accelerometers are given in Table 1.

Vibration sensing is required over a wide range of amplitudes and frequencies. For example, vibration from rotating machinery occurs from about 1 Hz to over 20,000 Hz, with the principal interest being from 10 to 2000 Hz. A smooth running motor may vibrate at $.01g$ ($1g = 386$ in./sec^2; 980 cm/sec^2), but a high-speed gearbox can easily vibrate at more than $100g$ at a frequency of over 10,000 Hz. Ideally, a vibration sensor attaches to a body in motion and provides an output signal proportional to the vibrational input from that body. See Fig. 1. Sometimes it is not practical to attach a sensor directly to the moving body. In those cases, the measurement is made by attaching the sensor to another body and making a measurement relative to the motion of that body. In any case, measurement performance must not be degraded because of the location of the sensor.

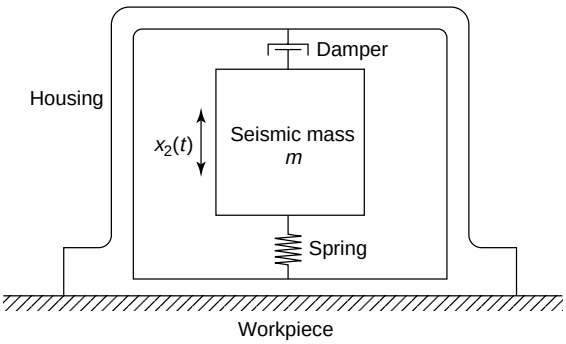

Fig. 1. Mechanical schematic of inertial sensor.

Piezoelectric Accelerometers. These devices utilize a mass in direct contact with a piezoelectric component, or crystal. When a varying motion is applied to the accelerometer, the crystal experiences a varying force excitation ($F = ma$) causing a proportional electrical charge q to be developed across it:

$$q = d_{ij}F = d_{ij}ma$$

where d_{ij} is the material's piezoelectric strain constant.

As the equation shows, the electrical output from the piezoelectric material is dependent on its properties. Two commonly used materials are lead zirconate titanate ceramic (PZT) and quartz. As self-generating materials, they both produce a large electrical charge for their size, although the piezoelectric strain constant of PZT is about 150 times that of quartz. As a result, accelerometers using PZT are more sensitive or are much smaller. The mechanical spring constants for the piezoelectric components are high and the inertial masses attached to them are small. Therefore, these accelerometers are useful to extremely high frequencies. Damping is rarely added to these devices. Fig. 2 shows a typical frequency response for such a device. Piezoelectric accelerometers have comparatively low mechanical impedance. Therefore, their effect on the motion of most structures is small. They are also rugged and have stable outputs with time and environment.

Two principal design configurations are used for piezoelectric accelerometers. One stresses the piezoelectric material in *compression* while

TABLE 1. TYPICAL ACCELEROMETER PERFORMANCE CHARACTERISTICS

Characteristics	Piezoelectric Accelerometers		Piezoresistive Accelerometer	Servo Accelerometer
Sensitivity, pC/g, mV/g	10	100	20	250
Frequency range, Hz	4-15,000	1-5,000	0-750	0-500
Resonance frequency, Hz	80,000	20,000	2,500	1,000
Amplitude range, g	500	1,000	25	15
Shock rating, g	2,000	10,000	2,000	250
Temperature range, °C	−50 to +125	−50 to +260	0 to +95	−40 to +85
Total mass, g	1	29	28	80

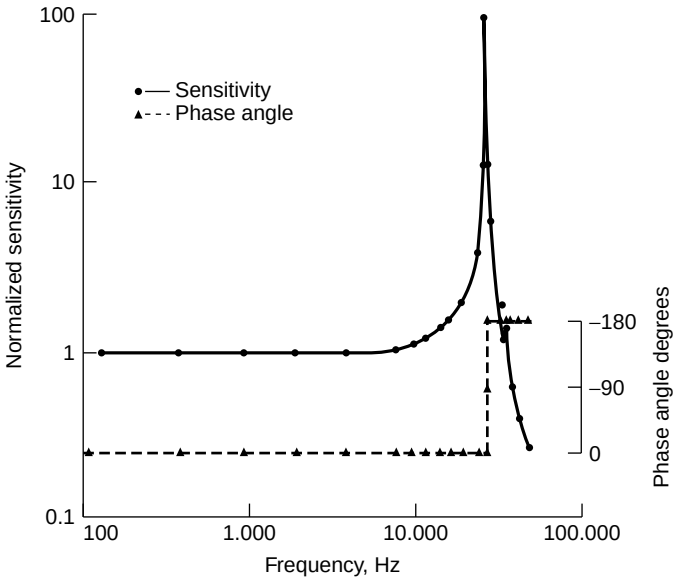

Fig. 2. Frequency response from typical piezoelectric accelerometer.

the other stresses it in *shear*. Simple diagrams of these are illustrated by Fig. 3. When the accelerometer is accelerated upward, the mass is moved downward toward the bottom of the accelerometer. Conversely, downward acceleration moves the mass element upward. With vibration motion, the resultant dynamic stress deforms the piezoelectric element. For the compression accelerometer, vibration varies the stress in the crystal which is held in compression by the pre-load element. For the shear accelerometer vibration simply deforms the crystal in shear. The mechanical construction for actual designs can be more complex, but the model is the same.

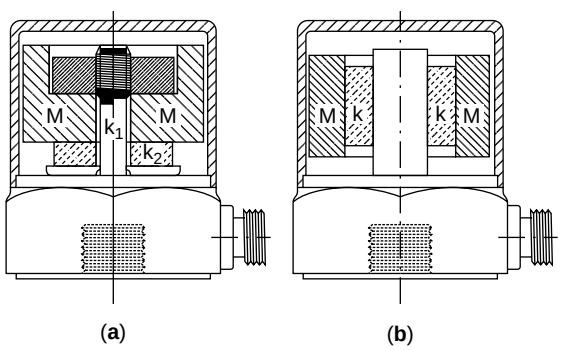

Fig. 3. Conceptual diagram for piezoelectric accelerometers: (**a**) compression, and (**b**) shear.

Piezoresistive Accelerometers and Strain-Gage Sensors. Piezoresistive accelerometers are strain gage sensors that use semiconductor strain gages in order to provide much greater gage factors than possible with metallic gages. Higher gage factors are achieved because the material resistivity changes with stress, not just its dimensions. The increased sensitivity is critical to vibration measurement in that it permits miniaturization of the accelerometer.

The typical piezoresistive accelerometer uses either two or four active gages in a Wheatstone bridge. It is more important to use multiple gages than when using metallic gages because the temperature coefficients of the semiconductor elements are greater than metallic gages. To control the electrical bridge balance and sensitivity variations with temperature, other resistors are used within the bridge and in series with the input.

The mechanical construction of an inertial system using piezoresistive elements is illustrated by Fig. 4. The construction of a complete accelerometer is shown by Fig. 5. This design includes overload stops to protect the gages from high amplitude inputs and includes oil to improve damping. Such an instrument is useful for acquiring vibration information at low frequencies (for example, below 1 Hz) and the device can be used to sense static acceleration.

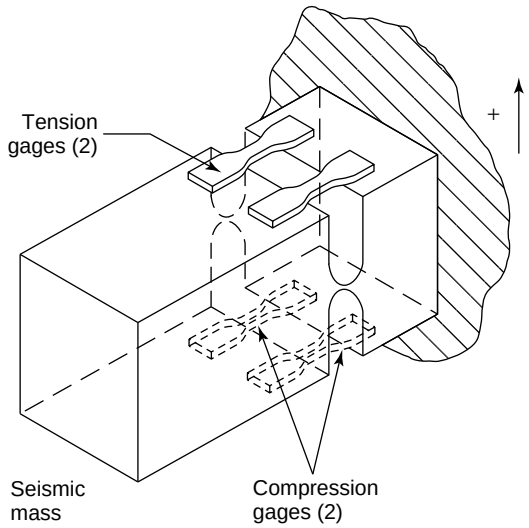

Fig. 4. Inertial system using piezoresistive elements.

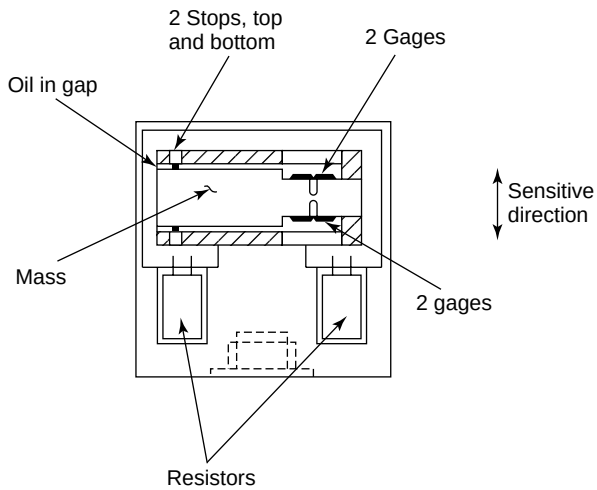

Fig. 5. Construction of typical piezoresistive elements.

Servo Accelerometers. The construction and operating principle of a servo accelerometer are illustrated by Fig. 6. When subjected to acceleration, the proof mass deflects relative to the base of the accelerometer, and the pickoff changes its capacitance as a result of changes in the damping gap. As this occurs, the servo supplies current to the coil that is located in the gaps of the permanent magnets. The resulting force restores the coil to its equilibrium position. The output signal is a measure of the coil current and is proportional to the applied acceleration.

Signal Conditioning for Accelerometers. Signal conditioners interface accelerometers to readout and processing instruments by (1) providing power to the accelerometer, if it is not self-generating, (2) providing proper electrical load to the accelerometer, (3) amplifying the signal, and (4) providing appropriate filtering and drive signal. Piezoelectric and piezoresistive transducers both require conditioners with certain characteristics as is now discussed.

Conditioning Piezoelectric Accelerometers. The piezoelectric accelerometer is self-generating and supplies a very small amount of energy to the signal conditioner. It presents a very high source impedance, mainly capacitive, to the conditioner. Two forms of schematic representation of a piezoelectric accelerometer are shown in Fig. 7. It may be regarded as a voltage source in series with a capacitance, or as a charge source in parallel with a capacitance. The signal conditioner determines how the transducer is treated in a given system. Both voltage and charge sensing are used. The charge amplifier is by far the most common approach. The charge amplifier is advantageous because the system gain and low frequency response are well defined and are independent of the cable length and accelerometer capacitance.

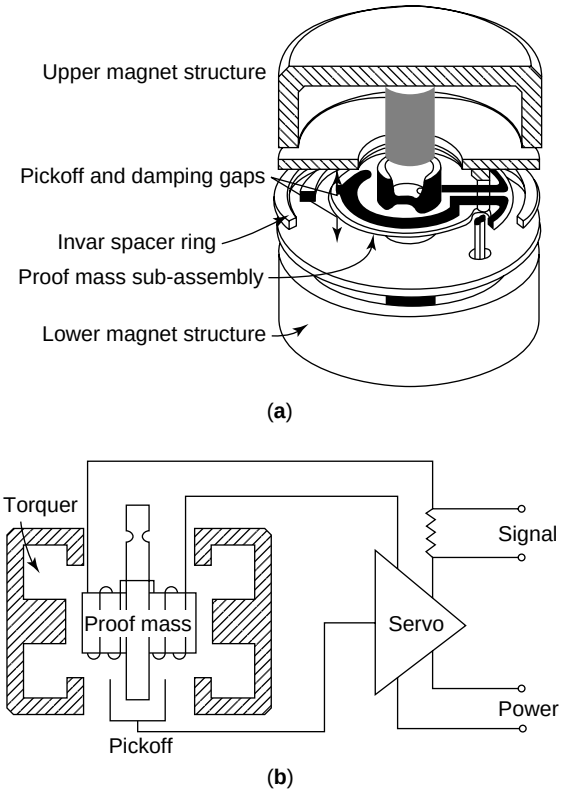

Fig. 6. Construction of serve accelerometer.

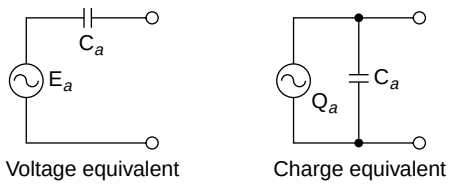

Fig. 7. Electrical schematic representation of piezoelectric accelerometers.

The charge amplifier consists of a charge converter and a voltage amplifier as shown in Fig. 8. The system does not amplify charge per se. It converts input charge to a voltage and then amplifies the voltage.

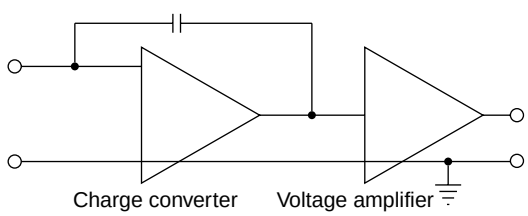

Fig. 8. Block diagram of charge amplifier.

A charge converter is essentially an operational amplifier with integrating feedback. The equivalent circuit is shown in Fig. 9. With basic operational type feedback, amplifier input is maintained at essentially zero volts and therefore looks like a short circuit to the input. Amplifier output is a function of input current. Having integrating operational feedback, output is the integral of input current. Hence the name "charge amplifier," since

$$q = \int i\,dt$$

In operation, the charge converter output voltage which occurs as a result of a charge input signal, is returned through the feedback capacitor to maintain the voltage at the input at, or close to, zero. Thus, the charge input is stored in the feedback capacitor, producing a voltage across it that is equal to the value of the charge input divided by the capacitance

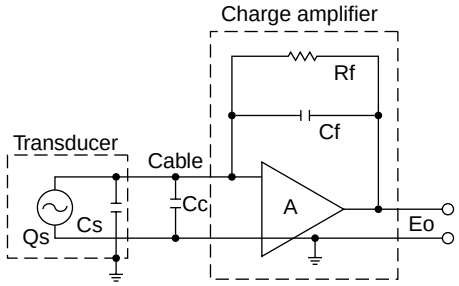

Fig. 9. Equivalent circuit of charge converter.

of the feedback capacitor. The transfer characteristic (charge gain) of this amplifier is therefore solely dependent upon the value of the feedback capacitor (or network if a more complicated feedback is used) provided that the amplifier's open loop gain and input impedance are sufficiently high. The midband charge gain (mV/pC) of this circuit is

$$\frac{E_o}{Q_i} = \frac{1}{C_f}$$

The complete circuit transfer function is given by:

$$\frac{E_o}{Q_i} = \frac{-A}{1+A} \cdot \frac{sR_f}{sR_f\left\{\dfrac{C_s + C_c}{1+A}\right\}C_f + 1}$$

where

E_o = charge converter output
Q_i = accelerometer signal (charge)
s = accelerometer sensitivity (charge)
C_a = accelerometer capacitance
C_c = cable capacitance
C_f = feedback capacitance
R_f = feedback resistance
A = amplifier open loop gain

To simplify, we can assume

$$\frac{-A}{1+A} = -1$$

since amplifier open loop gain A is very high and $A \approx 1 + A$.

Because C_f is very large compared to $(C_s + C_c)/(1 + A)$ in most applications, system gain is independent of cable length. Only an unlikely combination of extremely large source or cable capacitance and very small feedback capacitance would influence system gain, and then only to a minor degree. Therefore, charge measuring systems are seldom calibrated end-to-end.

With the above simplifications, the denominator of the expression becomes $sR_fC_f + 1$. This is the characteristic form of a simple first order roll off at

$$f_{-3\text{dB}} = \frac{1}{2R_fC_f}$$

with a terminal slope approaching 6 dB per octave. For all practical purposes, low frequency response of a charge measuring system is a function of well defined electronic components and does not vary with cable length. This is a very important feature when measuring low frequency vibrations.

Conditioning for Low Impedance Piezoelectric Accelerometers. Piezoelectric accelerometers are available with simple electronic circuits internal to their cases to provide signal amplification and low impedance output. Some designs operate from low-current dc voltage supplies and are designed to be *intrinsically safe* when coupled by appropriate barrier circuits. Other designs have common power and signal lines and use coaxial cables.

The principal advantages of piezoelectric accelerometers with integral electronics are their relative immunity to cable-induced noise and spurious response, the ability to use lower cost cable, and lower signal conditioning cost. In the simplest case, the power supply might consist of a battery, a resistor, and a capacitor.

These advantages do not come without compromise. Because the impedance matching circuitry is built into the transducer, gain cannot be

adjusted to utilize the wide dynamic range of the basic transducer. Ambient temperature is limited to that which the circuit will withstand, and this is considerably lower than that of the piezoelectric sensor itself. In order to retain the advantages of small size, the integral electronics must be kept relatively simple. This precludes the use of multiple filtering and dynamic overload protection and thus limits their application. But when conditions are relatively benign, these accelerometers can economically provide excellent noise immunity and signal fidelity.

Conditioning Piezoresistive Transducers. Piezoresistive transducers are relatively easy to condition. They generally have high level output, low output impedance, and very low intrinsic noise. These transducers require an external power supply. This supply is usually D.C., but it may be A.C. providing the carrier frequency is at least five to ten times the maximum frequency of interest.

Most transducers are designed for constant-voltage excitation and are used with relatively short cables. With long cables, wire resistance is not negligible. Moreover, resistance will change with temperature, and the voltage drop along the line will vary as transducer resistance or load changes. For these applications, transducers should be calibrated for constant-current excitation so their output will be less dependent upon external effects.

Many piezoresistive transducers are full-bridge devices. Some have four active arms to maximize sensitivity. See Fig. 10. Others have two active arms and two fixed precision resistor arms to permit shunt calibration by precision calibration resistors in the signal conditioner. Miniature transducers are usually half-bridge devices, with bridge completion accomplished in the signal conditioner.

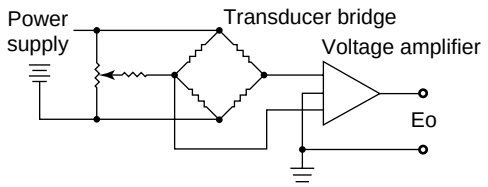

Fig. 10. Typical system and bridge circuit for piezoresistive accelerometer.

Adjustment of the unbalanced output of an accelerometer can easily be performed in the signal conditioner. For full-bridge transducers, the balancing potentiometer R_1 is connected across the excitation terminals and a current-limiting resistor is connected between the wiper arm of the potentiometer and the bridge.

Environmental Effects. *Temperatures* Accelerometers can be used over wide temperature ranges. Piezoelectric devices are available for use from cryogenic temperatures ($-270\,^{\circ}$C) to over $650\,^{\circ}$C. Sensitivity changes with ambient temperature, but the changes are systematic and can be calibrated. If the ambient temperature changes suddenly so that strains develop within the accelerometer and within the time response of the measurement system, further errors can occur. These are evaluated by testing the response of accelerometers to step function changes of temperature per industry standard test procedures. Errors usually appear as a wandering signal, or a low frequency oscillation.

Cable Movement. Cabling from the accelerometer to the signal conditioner can generate spurious signals when it is subjected to movement or dynamic forces. This is usually only significant for systems using high impedance piezoelectric accelerometers. The major noise generating mechanism is triboelectric noise. This is caused by charge trapping due to relative motion, or localized separation between the cable dielectric and the outer shield around the dielectric. To reduce this effect, cabling is available which is "noise treated." These cables have a conductive coating applied to the surface of the dielectric that prevents charge trapping. Another method used to eliminate this effect is to use a sensor that includes an electronic circuit to reduce the impedance to about 100 ohms.

Dynamic Strain Inputs. In vibration environments, some structures may dynamically flex, stretch, or bend at the mounting location of the accelerometer. The base of the accelerometer, being in intimate contact with this strained area, can also be strained. A portion of this base strain is transmitted directly to the crystal sensing element, and will generate error signals. In addition to strains in the structure, it is also possible to induce errors from forces or pressures onto the case of the accelerometer.

Electrostatic and Electromagnetic Fields. Electrostatic noise can be generated by stray capacitance coupling into the measurement system. It is important that the cabling between a high impedance piezoelectric sensor and the signal conditioner be fully shielded. Ground loops can be avoided by grounding the system at a single point, usually at the output of the signal conditioner.

Velocity Transducers. Electrodynamic velocity pickups have the capability of being used directly into readout instruments. The self-generating voltage in the transducer is proportional to the velocity of the motion being measured and is usually of sufficient amplitude so that no voltage amplification is required. The disadvantages of velocity pickups are their large size and mass and their inability to be used for measurements at frequencies below about 10 Hz. Also, the output at high frequencies, above about 1000 Hz, is quite small in most applications. Care must be taken in using these devices in strong magnetic field environments.

Relative Motion Sensing — Eddy Current Probe. In some cases, it is not practical to place a sensor in contact with the moving part. Relative motion measurement approaches are then used. The most commonly used device is the eddy current probe. Noncontact eddy current displacement measuring systems have achieved general acceptance for industrial machinery protection and condition monitoring. An eddy current displacement probe, generally about 0.300 in. (7.5 mm) in diameter, contains a small coil of fine wire at its tip which is excited by a remote radio frequency oscillator to generate a magnetic field. As the tip of the probe is brought close to a conductive surface, such as a rotating shaft, eddy currents induced in the conductor by the probe's magnetic field oppose the field and reduce the amplitude of the carrier by an amount proportional to the change in proximity. A demodulator, usually encapsulated in the same enclosure as the oscillator, converts the change in carrier amplitude to a low impedance, calibrated voltage output.

ACCLIMATIZATION. 1. The process by which a living organism becomes adapted to a change of climatic environment. There has been a growing amount of research on the acclimatization of man to extreme environments such as polar and tropical regions and high altitudes. Also called *acclimation.*

These studies are directed toward 1) determination of the internal physiological changes or skin changes produced by exposure to new climates, 2) determination of criteria for preselection (i.e., selecting the most adaptable type of man for a particular climate), and 3) development of external means of aiding adaptation (e.g., preconditioning, and modification of habits, diet, and clothing). As to usage, "acclimatization" has long been considered to be equivalent to "acclimation." In some quarters, however, a fine distinction is drawn by calling "acclimation" a purely natural process (or state), and "acclimatization" a process (or state) influenced by human agency. The recent trend, at least in the United States, is to use "acclimatization" as the all-inclusive technical term, and to leave "acclimation" (which never was accepted in Great Britain) to more or less loose popular usage. 2. The state or degree of adaptation to climate.

AMS

ACCOMMODATION COEFFICIENT. A quantity defined by the equation

$$a = \frac{T_3 - T_1}{T_2 - T_1}$$

where T_1 is the temperature of gas molecules striking a surface which is at temperature T_2, and T_3 is the temperature of the gas molecules as they leave the surface, a is the accommodation coefficient. It is, therefore, a measure of the extent to which the gas molecules leaving the surface are in thermal equilibrium with it.

ACCOMMODATION (Ocular). The mechanism whereby the equatorial diameter of the lens of the eye may be decreased and its thickness increased to focus clearly on the retina the image of a near object.

ACCRETION (Geology). The process by which crystals and other solid bodies grow by the addition of material onto their surfaces. A concretion is a body that grows from the center outward in a regular manner by successive additions of material.

ACCUMULATED COOLING. The total cooling since the time in the evening when the turbulent heat flux near the ground produces a net heat flow from the earth to the atmosphere; used to measure or predict evolution of the stable boundary layer.

It is defined as the integral of the surface kinematic heat flux $\overline{w'\theta'_s}$ over time, starting from the time t_0 just before sunset when the flux changes from positive to negative, and ending at any time t_e before the flux changes sign back to positive. Dimensions are temperature times length, such as (K·m). In the absence of advection and direct radiative cooling of the air, accumulated cooling (AC) also equals the area under the potential temperature profile $z(\theta)$, integrated from the surface potential temperature θ_s to the residual-layer potential temperature θ_{RL}, that is,

$$\mathrm{AC} \equiv \int_{t_0}^{t} \overline{w'\theta'_s}\, \mathrm{d}t \approx \int_{\theta_t}^{\theta_{kL}} z(\theta) d\theta.$$

AMS

ACCUMULATED TEMPERATURE (or cumulative temperature). In Great Britain, the accumulated excess of temperature above a given standard temperature. It is expressed in degree-hours or degree-days. For each day, degree-hours are determined as the product of the length of time, in hours, during which temperatures are above the standard, and the amount, in degrees, by which the mean temperature of the period exceeds the standard. Division of the resulting degree-hour value by 24 gives a value in degree-days. Summation of either over the period of interest creates the accumulated temperature. The concept of accumulated temperature was introduced into plant geography by A. de Candolle (1855); his standard temperature was 6 °C (42.8 °F), below which he considered that no vegetative growth took place. It was introduced into agricultural meteorology in Britain in 1878, when accumulated temperatures in excess of 42 °F were first published regularly in the Weekly Weather Report. These were calculated from the daily maximum and minimum temperatures. In heating calculations, a form of accumulated temperature is calculated as the number of degree-days below the standard, which is taken as 65 °F (18 °C) in the United States and 60 °F (16 °C) in Great Britain. Since the standard temperatures differ, degree-days are not interchangeable between the two countries.

ACCUMULATOR (Hydraulic). The hydraulic accumulator is a hydraulic device consisting of a cylinder and piston that is actuated by weight, springs, or compressed fluid. On the opposite side of the piston a fluid such as water, oil, air, etc., is stored and, consequently, is available to do work when the pressure on it is reduced. This work is obtained by virtue of the fact that while the fluid is discharged rapidly, giving large hydraulic power for short periods of time, it may be refilled by a comparatively small and low-powered pump working a much longer period of time.

One successful type of accumulator consists of a closed cylinder containing a rubber bag filled with air or gas. Fluid is pumped into the cylinder under pressure, compressing the air or gas in the bag. When the release valve is opened the air or gas in the bag expands to eject the fluid from the cylinder.

Another type of hydraulic accumulator is the pumped storage plant, used in electric power systems for the economic carrying of variable loads. As employed in conjunction with steam generating stations, steam turbine-driven centrifugal pumps raise water from a lower to an upper pool with off-peak power. During the peak-load periods this water is released to the lower pool through a hydraulic turbo-generator as rapidly as is needed to give the required power. In favorable locations the overall efficiency of conversion and storage need not be greater than 50% in order to justify the project. See also **Hydroelectric Power**.

ACCURACY. In terms of instruments and scientific measuring systems, accuracy may be defined as the conformity of an indicated value to an accepted standard value, or true value. Accuracy is usually measured in terms of *inaccuracy* and expressed as *accuracy*. As a performance specification, accuracy should be assumed to mean *reference accuracy* unless otherwise stated.

Reference accuracy may be defined as a number or quantity which defines the limit that errors will not exceed when the device is used under reference operating conditions. See Fig. 1. Reference accuracy includes the combined conformity, hysteresis, and repeatability errors. The units being used must be stated explicitly. It is preferred that a + and − sign precede the number or quantity. The absence of a sign infers both a plus and a minus sign. Reference accuracy can be expressed in a number of forms, of which the five following examples are typical:

(1) Reference accuracy expressed in terms of the *measured variable*. Typical expression: The reference accuracy is ±1 °F (±0.6 °C).

(2) Reference accuracy expressed in percent of *span*. Typical expression: The reference accuracy is ±1/2% of span. This percentage is calculated using units, such as deg. F or C, psi, and so on.

(3) Reference accuracy expressed in percent of the *upper range-value*. Typical expression: The reference accuracy is ±1/2% of upper range-value. This percentage is also calculated, using units as previously given.

(4) Reference accuracy expressed in percent of *scale length*. Typical expression: The reference accuracy is ±1/2% of scale length.

(5) Reference accuracy expressed in percent of *actual output reading*. Typical expression: The reference accuracy is ±1% of actual output reading. Again, this percentage is calculated, using scale units such as previously given.

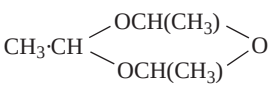
ACETALDEHYDE. Acetaldehyde [CAS: 75-07-0]. CH_3CHO, formula weight 44.05, colorless, odorous liquid, mp −123.5 °C, bp 20.2 °C, sp gr 0.783. Also known as *ethanal*, acetaldehyde is miscible with H_2O, alcohol, or ether in all proportions. Because of its versatile chemical reactivity, acetaldehyde is widely used as a commencing material in organic syntheses, including the production of resins, dyestuffs, and explosives. The compound also is used as a reducing agent, preservative, and as a medium for silvering mirrors. In resin manufacture, paraldehyde [CAS: 123-63-7] $(CH_3CHO)_3$ sometimes is preferred because of its higher boiling and flash points.

In tonnage production, acetaldehyde may be manufactured by:

1. The direct oxidation of ethylene, requiring a catalytic solution of copper chloride plus small quantities of palladium chloride [CAS: 7647-10-1] Cl_2Pd.
2. The oxidation of ethyl alcohol [CAS: 64-17-5] C_2H_6O with sodium dichromate [CAS: 10588-01-9] $Cr_2Na_2O_7$, and
3. The dry distillation of calcium acetate [CAS: 5743-26-0] $C_4H_6CaO_4$ with calcium formate [CAS: 544-17-2] $C_2H_2CaO_4$.

Acetaldehyde reacts with many chemicals in a marked manner, (1) with ammonio-silver nitrate ("Tollen's solution"), to form metallic silver, either as a black precipitate or as an adherent mirror film on glass, (2) with alkaline cupric solution ("Fehling's solution") to form cuprous oxide, red to yellow precipitate, (3) with rosaniline (fuchsine, magenta), which has been decolorized by sulfurous acid ("Schiff's solution"), the pink color of rosaniline is restored, (4) with NaOH, upon warming, a yellow to brown resin of unpleasant odor separates (this reaction is given by aldehydes immediately following acetaldehyde in the series, but not by formaldehyde [CAS: 50-00-0] CH_2O, furfuraldehyde, or benzaldehyde) [CAS: 100-52-7] C_7H_6O, (5) with anhydrous ammonia, to form aldehyde-ammonia $CH_3{\cdot}CHOH{\cdot}NH_2$, white solid, mp 97 °C, bp 111 °C, with decomposition, (6) with concentrated H_2SO_4, heat is evolved, and with rise of temperature, paraldehyde $(C_2H_4O)_3$ or



a colorless liquid, bp 124 °C, slightly soluble in H_2O, is formed, (7) with acids, below 0 °C, forms metaldehyde [CAS: 9002-91-9] $(C_2H_4O)x$, white solid, sublimes at about 115 °C without melting but with partial conversion to acetaldehyde, (8) with dilute HCl or dilute NaOH, aldol, $CH_3{\cdot}CHOH{\cdot}CH_2CHO$ slowly forms, (9) with phosphorus pentachloride, [CAS: 10026-13-8] Cl_5P, forms ethylidene chloride, [CAS: 75-34-3], $CH_3{\cdot}CHCl_2$, colorless liquid, bp 58 °C, (10) with ethyl alcohol [CAS: 64-17-5], C_2H_6O and dry hydrogen chloride, forms acetal, 1,1-diethyoxyethane $CH_3{\cdot}CH(OC_2H_5)_2$, colorless liquid, bp 104 °C, (11) with hydrocyanic acid, forms acetaldehyde cyanohydrin, $CH_3{\cdot}CHOH{\cdot}CN$, readily converted into alpha-hydroxypropionic acid, $CH_3{\cdot}CHOH{\cdot}COOH$, (12) with sodium hydrogen sulfite, forms acetaldehyde sodium bisulfite, $CH_3{\cdot}CHOH{\cdot}SO_3Na$, white solid, from which acetaldehyde is readily recoverable by treatment with sodium carbonate solution, (13) with hydroxylamine hydrochloride forms acetaldoxime, $CH_3{\cdot}CH{:}NOH$, white solid, mp 47 °C, (14) with phenylhydrazine, forms acetaldehyde phenylhydrazone, $CH_3{\cdot}CH{:}N{\cdot}NH{\cdot}C_6H_5$, white solid, mp 98 °C, (15) with magnesium methyl iodide in anhydrous ether ("Grignard's solution"), yields, after reaction with water, isopropyl alcohol, $(CH_3)_2CHOH$, a secondary alcohol, (16) with semicarbazide, forms acetaldehyde semicarbazone, $CH_3{\cdot}CH{:}N{\cdot}NH{\cdot}CO{\cdot}NH_2$, white solid, mp 162 °C, (17) with chlorine, forms trichloroacetaldehyde ("chloral"), $CCl_3{\cdot}CHO$, (18) with H_2S, forms thioacetaldehyde, $CH_3{\cdot}CHS$ or $(CH_3{\cdot}CHS)_3$. Acetaldehyde stands chemically between ethyl alcohol on one hand — to which it can be reduced — and acetic acid on the other hand — to which it can be oxidized. These reactions of acetaldehyde, coupled with its ready formation from acetylene by mercuric sulfate solution as a catalyzer, open up a vast field of organic chemistry with acetaldehyde as raw material: acetaldehyde hydrogenated to ethyl alcohol; oxygenated to acetic acid, thence to acetone, acetic anhydride, vinyl acetate, vinyl alcohol. Acetaldehyde is also formed by the regulated oxidation of ethyl alcohol by such a reagent as sodium dichromate in H_2SO_4 (chromic sulfate also produced). Reactions (1), (3), (14), and (16) above are most commonly used in the detection of acetaldehyde. See also **Aldehydes**.

ACETAL GROUP. An organic compound of the general formula $RCH(OR')(OR'')$ is termed an *acetal* and is formed by the reaction of an aldehyde with an alcohol, usually in the presence of small amounts of acids or appropriate inorganic salts. Acetals are stable toward alkali, are volatile, insoluble in H_2O, and generally are similar structurally to ethers. Unlike ethers, acetals are hydrolyzed by acids into their respective aldehydes. $H(R)CO + (HO{\cdot}C_2H_5)_2 \rightarrow H(R)C(OC_2H_5)_2 + H_2O$. Representative acetals include: $CH_2(OCH_3)_2$, methylene dimethyl ether, bp 42 °C; $CH_3CH(OCH_3)_2$, ethylidene dimethyl ether, bp 64 °C; and $CH_3CH(OC_2H_5)_2$, ethylidene diethyl ether, bp 104 °C.

ACETAL RESINS. A very useful family of thermoplastic resins, obtainable both as homopolymers and copolymers, produced mainly from formaldehyde or a formaldehyde derivative. Acetals have the highest fatigue endurance of commercial thermoplastics. In their manufacture, a variety of ionic initiators, such as tertiary amines and quaternary ammonium salts, are used to effect polymerization of formaldehyde. Chain transfer controls the molecular weight of the resulting resins.

Starting ingredients may be formaldehyde or the cyclic trimer trioxane. Both form polymers of similar properties. Boron trifluoride or other Lewis acids are used to promote polymerization where trioxane is the raw material.

Acetals provide excellent resistance to most organic compounds except when exposed for long periods at elevated temperatures. The resins have limited resistance to strong acids and oxidizing agents. The copolymers and some of the homopolymers are resistant to the action of weak bases. Normally, where resistance to burning, weathering, and radiation are required, acetals are not specified. The resins are used for cams, gears, bearings, springs, sprockets, and other mechanical parts, as well as for electrical parts, housings, and hardware.

ACETATE DYE. One group comprises water insoluble azo or anthraquinone dyes that have been highly dispersed to make them capable of penetrating and dyeing acetate fibers. A second class consists of water-insoluble amino azo dyes that are made water soluble by treatment with formaldehyde and bisulfite. After absorption by the fiber, the resulting sulfonic acids hydrolyze and regenerate the insoluble dyes.

See also **Dyes and Dye Intermediates**; and **Dyes: Anthraquinone**.

ACETATE FIBERS. See **Fibers (Acetate)**.

ACETATES. See **Acetic Acid**; and **Fibers (Acetate)**.

ACETIC ACID. Acetic acid [CAS: 64-19-7] CH_3COOH, formula weight 60.05, colorless, acrid liquid, mp 16.7 °C, bp 118.1 °C, sp gr 1.049. Also known as ethanoic acid or vinegar acid, this compound is miscible with H_2O, alcohol, and ether in all proportions. Acetic acid is available commercially in several concentrations. The CH_3COOH content of glacial acetic is approximately 99.7% with H_2O, the principal impurity. Reagent acetic acid generally contains 36% CH_3COOH by weight. Standard commercial aqueous solutions are 28, 56, 70, 80, 85, and 90% CH_3COOH. Acetic acid is the active ingredient in vinegar in which the content ranges from 4 to 5% CH_3COOH. Acetic acid is classified as a weak, monobasic acid. The three hydrogen atoms linked to one of the two carbon atoms are not replaceable by metals.

In addition to the large quantities of vinegar produced, acetic acid in its more concentrated forms is an important high-tonnage industrial chemical, both as a reactive raw and intermediate material for various organic syntheses and as an excellent solvent. Acetic acid is required in the production of several synthetic resins and fibers, pharmaceuticals, photographic chemicals, flavorants, and bleaching and etching compounds.

Early commercial sources of acetic acid included (1) the combined action of *Bacterium aceti* and air on ethyl alcohol in an oxidation-fermentation process: $C_2H_5OH + O_2 \rightarrow CH_3COOH + H_2O$, the same reaction which occurs when weak alcoholic beverages, such as beer or wine, are exposed to air for a prolonged period and which turn sour because of the formation of acetic acid; and (2) the destructive distillation of wood. A number of natural vinegars still are made by fermentation and marketed as the natural product, but diluted commercially and synthetically produced acetic acid is a much more economic route to follow. The wood distillation route was phased out because of shortages of raw materials and the much more attractive economy of synthetic processes.

The most important synthetic processes are (1) the oxidation of acetaldehyde, and (2) the direct synthesis from methyl alcohol and carbon monoxide. The latter reaction must proceed under very high pressure (approximately 650 atmospheres) and at about 250 °C. The reaction takes place in the liquid phase and dissolved cobaltous iodide is the catalyst. $CH_3OH + CO \rightarrow CH_3COOH$ and $CH_3OCH_3 + H_2O + 2CO \rightarrow 2CH_3COOH$. The crude acid produced first is separated from the catalyst and then dehydrated and purified in an azeotropic distillation column. The final product is approximately 99.8% pure CH_3COOH.

Acetic acid solution reacts with alkalis to form acetates, e.g., sodium acetate, calcium acetate; similarly, with some oxides, e.g., lead acetate; with carbonates, e.g., sodium acetate, calcium acetate, magnesium acetate; with some sulfides, e.g., zinc acetate, manganese acetate. Ferric acetate solution, upon boiling, yields a red precipitate of basic ferric acetate. Acetic acid solution attacks many metals, liberating hydrogen and forming acetate, e.g., magnesium, zinc, iron. Acetic acid is an important organic substance, with alcohols forming esters (acetates); with phosphorus trichloride forming acetyl chloride $CH_3CO \cdot Cl$, which is an important reagent for transfer of the acetyl (CH_3CO-) group; forming acetic anhydride, also an acetyl reagent; forming acetone and calcium carbonate when passed over lime and a catalyzer (barium carbonate) or when calcium acetate is heated; forming methane (and sodium carbonate) when sodium acetate is heated with NaOH; forming mono-, di-, tri-chloroacetic (or bromoacetic) acids by reaction with chlorine (or bromine) from which hydroxy- and amino-, aldehydic-, dibasic acids, respectively, may be made; forming acetamide when ammonium acetate is distilled. Acetic acid dissolves sulfur and phosphorus, is an important solvent for organic substances, and causes painful wounds when it comes in contact with the skin. Normal acetates are soluble, basic acetates insoluble. The latter are important in their compounds with lead, and copper ("verdigris").

A large number of acetic acid esters are important industrially, including methyl, ethyl, propyl, butyl, amyl, and cetyl acetates; glycol mono- and diacetate; glyceryl mono-, di-, and triacetate; glucose pentacetate; and cellulose tri-, tetra-, and pentacetate.

Acetates may be detected by formation of foul-smelling cacodyl (poisonous) on heating with dry arsenic trioxide. Other tests for acetate are the lanthanum nitrate test in which a blue or bluish-brown ring forms when a drop of 2.5% $La(NO)_3)_3$ solution, a drop of 0.01-N iodine solution, and a drop of 0.1% NH_4OH solution are added to a drop of a neutral acetate solution; the ferric chloride test, in which a reddish color is produced by the addition of 1-*N* ferric chloride solution to a neutral solution of acetate; and the ethyl acetate test, in which ethyl alcohol and H_2SO_4 are added to the acetate solution and warmed to form a colorless solution.

ACETOACETIC ESTER CONDENSATION. A class of reactions occasioned by the dehydrating power of metallic sodium or sodium ethoxide on the ethyl esters of monobasic aliphatic acids and a few other esters. It is best known in the formation of acetoacetic ester:

$$2\ CH_3 \cdot COOC_2H_5 + 2\ CH_3 \cdot COOC_2H_5 + 2\ Na \longrightarrow$$
$$2\ CH_3 \cdot C(ONa){:}CH \cdot COOC_2H_5 + 2\ C_2H_5OH + H_2$$

The actual course of the reaction is complex. By the action of acids the sodium may be eliminated from the first product of the reaction and the free ester obtained. This may exist in the tautomeric enol and keto forms ($CH_3 \cdot COH{:}CH \cdot COOC_2H_5$ and $CH_3 \cdot CO \cdot CH_2 \cdot COOC_2H_5$).

On boiling ester with acids or alkalies it will split in two ways, the circumstances determining the nature of the main product. Thus, if moderately strong acid or weak alkali is employed, acetone is formed with very little acetic acid (ketone splitting). In the presence of strong alkalies, however, very little acetone and much acetic acid result (acid splitting). Derivatives of acetoacetic ester may be decomposed in the same fashion, and this fact is responsible for the great utility of this condensation in organic synthesis. This is also due to the reactivity of the $\cdot CH_2 \cdot$ group, which reacts readily with various groups, notably halogen compounds. Usually the sodium salt of the ester is used, and the condensation is followed by decarboxylation with dilute alkali, or deacylation with concentrated alkali.

$$CH_3 \cdot CO \cdot CHNa \cdot COOC_2H_5 + RI \longrightarrow$$
$$CH_3 \cdot CO \cdot CHR \cdot COOC_2H_5 + NaI$$

$$CH_3 \cdot CO \cdot CHR \cdot COOC_2H_5 \xrightarrow[\text{Dilute alkali}]{H_2O}$$
$$CH_3 \cdot CO \cdot CH_2R + C_2H_5OH + CO_2$$

$$CH_3 \cdot CO \cdot CHR \cdot COOC_2H_5 \xrightarrow[\text{Concentrated alkali}]{2\ H_2O}$$
$$HOOC \cdot CH_2 \cdot R + C_2H_5OH + CH_3COOH$$

ACETONE. $CH_3 \cdot CO \cdot CH_3$, [CAS: 67-64-1] formula weight 58.08, colorless, odorous liquid ketone, mp −94.6 °C, bp 56.5 °C, sp gr 0.792. Also known as dimethyl ketone or propanone, this compound is miscible in all proportions with H_2O, alcohol, or ether. Acetone is a very important solvent and is widely used in the manufacture of plastics and lacquers. For storage purposes, acetylene may be dissolved in acetone. A high-tonnage chemical, acetone is the starting ingredient or intermediate for numerous organic syntheses. Closely related, industrially important compounds are diacetone alcohol (DAA) [CAS: 18001-79-4] $CH_3 \cdot CO \cdot CH_2 \cdot COH(CH_3)_2$ which is used as a solvent for cellulose acetate and nitrocellulose, as well as for various resins and gums, and as a thinner for lacquers and inking materials. Sometimes DAA is mixed with castor oil for use as a hydraulic brake fluid for which its physical properties are well suited, mp −54 °C, bp 166 °C, sp gr 0.938. A product known as synthetic methyl acetone is prepared by mixing acetone (50%), methyl acetate (30%), and methyl alcohol (20%) and is used widely for coagulating latex and in paint removers and lacquers.

In older industrial processes, acetone is prepared (1) by passing the vapors of acetic acid over heated lime. In a first step, calcium acetate is produced, followed by a breakdown of the acetate into acetone and calcium carbonate:

$$CH_3 \cdot CO \cdot O \cdot Ca \cdot OOC \cdot CH_3 \longrightarrow CH_3 \cdot CO \cdot CH_3 + CaCO_3;$$

and (2) by fermentation of starches, such as maize, which produce acetone along with butyl alcohol. Modern industrial processes include (3) the use of cumene as a charge stock, in which cumene first is oxidized to cumene hydroperoxide (CHP), this followed by the decomposition of CHP into acetone and phenol; and (4) by the direct oxidation of propylene, using air and catalysts. The catalyst solution consists of copper chloride and small amounts of palladium chloride. The reaction: $CH_3CHC{=}H_2 + 1/2\ O_2 \rightarrow CH_3COCH_3$. During the reaction, the palladium chloride is reduced to elemental palladium and HCl. Reoxidation is effected by cupric chloride. The cuprous chloride resulting is reoxidized during the catalyst regeneration cycle. The process is carried out under moderate pressure at about 100 °C.

Acetone reacts with many chemicals in a marked manner: (1) with phosphorus pentachloride, yields acetone chloride $(CH_3)_2CCl_2$, (2) with hydrogen chloride dry, yields both mesityl oxide $CH_3COCH{:}C(CH_3)_2$, liquid, bp 132 °C, and phorone $(CH_3)_2C{:}CHCOCH : C(CH_3)_2$, yellow solid, mp 28 °C, (3) with concentrated H_2SO_4, yields mesitylene $C_6H_3(CH_3)_3$ (1,3,5), (4) with NH_3, yields acetone amines, e.g., diacetoneamine $C_6H_{12}ONH$, (5) with HCN, yields acetone cyanohydrin $(CH_3)_2CHOH \cdot CN$, readily converted into alpha-hydroxy acid $(CH_3)_2CHOH \cdot COOH$, (6) with sodium hydrogen sulfite, forms acetone-sodiumbisulfite $(CH_3)_2\ COH \cdot SO_3Na$ white solid, from which acetone is readily recoverable by treatment with sodium carbonate solution, (7) with hydroxylamine hydrochloride, forms acetoxime $(CH_3)_2C{:}NOH$, solid, mp 60 °C, (8) with phenylhydrazine, yields acetonephenyl-hydrazone $(CH_3)_2C{:}NNHC_6H_5 \cdot H_2O$, solid, mp 16 °C, anhydrous compound, mp 42 °C, (9) with semicarbazide, forms acetonesemicarbazone $(CH_3)C{:}NNHCONH_2$, solid, mp 189 °C, (10) with magnesium methyl iodide in anhydrous ether ("Grignard's solution"), yields, after reaction with H_2O, trimethylcarbinol $(CH_3)_3COH$, a tertiary alcohol, (11) with ethyl thioalcohol and hydrogen chloride dry, yields mercaptol $(CH_3)_2C(SC_2H_5)_2$, (12) with hypochlorite, hypobromite, or hypoiodite solution, yields chloroform $CHCl_3$, bromoform $CHBr_3$ or iodoform CHI_3, respectively, (13) with most reducing agents, forms isopropyl alcohol $(CH_3)_2CHOH$, a secondary alcohol, but with sodium amalgam forms pinacone $(CH_3)_2COH \cdot COH(CH_3)_2$ (14) with sodium dichromate

and H_2SO_4, forms acetic acid CH_3COOH plus CO_2. When acetone vapor is passed through a tube at a dull red heat, ketene CH_2:CO and methane CH_4 are formed.

ACETYL CHLORIDE. See **Chlorinated Organics**.

ACETYLCHOLINE. Acetylcholine [CAS: 51-84-3] is a neurotransmitter found in the nervous systems of all animals. It is involved in the control of functions as diverse as locomotion, digestion, cardiac rate, "fight and flight" responses, secretion, learning and memory. Cholinergic dysfunction is associated with neuromuscular diseases such as myasthenia gravis and neurodegenerative disorders such as Alzheimer disease.

Studies of acetylcholine and cholinergic neurotransmission have played a key role in the development of nearly all aspects of our current understanding of chemical synaptic transmission. In the early part of the twentieth century, pioneering physiological and neurochemical experiments resulted in establishing the principle that release of neuroactive compounds, such as acetylcholine, on to effector cells or other neurons forms the basis of most types of intercellular communication. In these early studies, application of acetylcholine could mimic the effects of nerve stimulation on muscle contraction, the rate of heart beating, etc., and the compound was thus identified as the first neurotransmitter substance. It was also noted that not all nerves released acetylcholine when stimulated, thus indicating specificity for the type of neurotransmitter substances present in particular neurons. Pharmacological work identified compounds, extracted primarily from plants, which differentially blocked the action of acetylcholine on particular types of effector cells, leading to the concept of receptor specificity. The quantal nature of neurotransmitter release was also first appreciated at cholinergic neuromuscular junctions. Finally, the nicotinic acetylcholine receptor was the first ligand-gated ion channel to have its amino acid sequence established. See also **Neurotransmitters**.

Acetylcholine is a simple ester of the quaternary amino alcohol choline and acetic acid. Acetylcholine is positively charged at physiological pH, is freely soluble in water (usually supplied as a bromide or chloride salt) and is subject to rapid hydrolysis in solution by heat or alkali. Nuclear magnetic resonance studies indicate considerable flexibility of the molecule in solution, and different conformations are thought to bind to different types of acetylcholine receptor.

Acetylcholine functions primarily as a chemical neurotransmitter in the nervous systems of all animals. When a cholinergic neuron is excited, it releases transmitter into the synaptic cleft where it can bind to a number of different receptor proteins. The receptors for acetylcholine can be classified into two general categories based primarily on the actions of different plant alkaloids that affect their function: nicotinic (nicotine binding) or muscarinic (muscarine binding). Several different subtypes for each of these general receptor classes have been characterized. The receptor binding event can be transduced into opening of cationic or anionic ion channels or coupled to some other metabolic signal such as phospholipid turnover rates or activation of second-messenger systems. Both inhibitory or, more commonly, excitatory responses are induced in the neurons or effector cells which receive the neurotransmitter signal, making acetylcholine-mediated neurotransmission particularly versatile.

In addition to the ubiquitous presence of acetylcholine in the nervous systems of all animals, it is also found in a limited number of plants, bacteria, fungi and protozoa. This widespread distribution in a variety of species most likely indicates the appearance of acetylcholine-metabolizing proteins fairly early in evolutionary history. In vertebrates, acetylcholine is also found in non-neuronal tissues such as primate placenta and sperm where its functional role, if any, remains unknown.

PAUL M. SALVATERRA, Beckman Research Institute, Duarte, CA

ACETYLENE. Acetylene, [CAS: 74-86-2], CH:CH formula weight 26.04, mp $-81.5\,^{\circ}C$, bp $-84\,^{\circ}C$, sp gr 0.905 (air = 1.000). Sometimes referred to as ethyne, ethine, or gaseous carbon (92.3% of the compound is C), acetylene is moderately soluble in H_2O or alcohol, and exceptionally soluble in acetone (300 volumes of acetylene in 1 volume of acetone at 12 atmospheres pressure). The gas burns when ignited in air with a luminous sooty flame, requiring a specially devised burner for illumination purposes. An explosive mixture is formed with air over a wide range (about 3 to 80% acetylene), but safe handling is improved when the gas is dissolved in acetone. The heating value is 1455 Btu/ft^3 (8.9 Cal/m^3).

Although acetylene still is used in a number of organic syntheses on an industrial scale, its use on a high-tonnage basis has diminished because of the lower cost of other starting materials, such as ethylene and propylene. Acetylene has been widely used in the production of halogen derivatives, acrylonitrile, acetaldehyde, and vinyl chloride. Within recent years, producers of acrylonitrile switched to propylene as a starting material.

Commercially, acetylene is produced from the pyrolysis of naphtha in a two-stage cracking process. Both acetylene and ethylene are end products. The ratio of the two products can be changed by varying the naphtha feed rate. Acetylene also has been produced by a submerged-flame process from crude oil. In essence, gasification of the crude oil occurs by means of the flame, which is supported by oxygen beneath the surface of the oil. Combustion and cracking of the oil take place at the boundaries of the flame. The composition of the cracked gas includes about 6.3% acetylene and 6.7% ethylene. Thus, further separation and purification are required. Several years ago when procedures were developed for the safe handling of acetylene on a large scale, J. W. Reppe worked out a series of reactions that later became known as "Reppe chemistry." These reactions were particularly important to the manufacture of many high polymers and other synthetic products. Reppe and his associates were able to effect synthesis of chemicals that had been commercially unavailable. An example is the synthesis of cyclooctatetraene by heating a solution of acetylene under pressure in tetrahydrofuran in the presence of a nickel cyanide catalyst. In another reaction, acrylic acid was produced from CO and H_2O in the presence of a nickel catalyst: $C_2H_2 + CO + H_2O \rightarrow CH_2$:CH·COOH. These two reactions are representative of a much larger number of reactions, both those that are straight-chain only, and those involving ring closure.

Acetylene reacts (1) with chlorine, to form acetylene tetrachloride [CAS: 79-34-5] $C_2H_2Cl_4$ or $CHCl_2{\cdot}CHCl_2$ or acetylene dichloride [CAS: 540-59-0] $C_2H_2Cl_2$ or CHCl:CHCl, (2) with bromine, to form acetylene tetrabromide [CAS: 79-27-6] $C_2H_2Br_4$ or $CHBr_2{\cdot}CHBr_2$ or acetylene dibromide [CAS: 540-49-8] $C_2H_2Br_2$ or CHBr:CHBr, (3) with hydrogen chloride (bromide, iodide), to form ethylene monochloride [CAS: 75-01-4] CH_2:CHCl (monobromide, monoiodide), and 1,1-dichloroethane, ethylidene chloride $CH_3{\cdot}CHCl_2$ (dibromide, diiodide), (4) with H_2O in the presence of a catalyzer, e.g., mercuric sulfate [CAS: 7783-35-9] HgO_4S, to form acetaldehyde $CH_3{\cdot}CHO$, (5) with hydrogen, in the presence of a catalyzer, e.g., finely divided nickel heated, to form ethylene [CAS: 74-85-1] C_2H_4 or ethane [CAS: 74-84-0] C_2H_6, (6) with metals, such as copper or nickel, when moist, also lead or zinc, when moist and unpurified. Tin is not attacked. Sodium yields, upon heating, the compounds C_2HNa and C_2Na_2. (7) With ammoniocuprous (or silver) salt solution, to form cuprous (or silver) acetylide C_2Cu_2, dark red precipitate, explosive when dry, and yielding acetylene upon treatment with acid, (8) with mercuric chloride solution, to form trichloromercuric acetaldehyde $C(HgCl)_3{\cdot}CHO$, precipitate, which yields with HCl acetaldehyde plus mercuric chloride.

ACETYLENE SERIES. A series of unsaturated hydrocarbons having the general formula C_nH_{2n-2}, and containing a triple bond between two carbon atoms. The series is named after the simplest compound of the series, acetylene HC:CH. In more modern terminology, this series of compounds is termed the *alkynes*. See also **Alkynes**.

ACETYLSALICYLIC ACID. Acetylsalicylic Acid [CAS: 50-78-2]. $C_6H_4(COOH)CO_2CH_3$, formula wt, 180.06, mp 133.5 °C, colorless, crystalline, slightly soluble in water, soluble in alcohol and ether, commonly known as aspirin, also called orthoacetoxybenzoic acid. The substance is commonly used as a relief for mild forms of pain, including headache and joint and muscle pain. The drug tends to reduce fever. Aspirin and other forms of salicylates have been used in large doses in acute rheumatic fever, but must be administered with extreme care in such cases by a physician. Commercially available aspirin is sometime mixed with other pain relievers as well as buffering agents.

See also **Aspirin**; and **Salicylic Acid and Related Compounds**.

ACHENE. A single-seeded, indehiscent fruit, in which the seed is free from the ovary wall except at the point of attachment. An example is the sunflower "seed."

ACHERNAR (α Eridani). Ranking tenth in apparent brightness among the stars, Achernar has a true brightness value of 200 as compared with unity for the sun. Achernar is a blue-white, spectral B type star and is one of the end stars in the constellation Eridanus, located south of the ecliptic and in the viewing vicinity of the Magellanic Clouds. Estimated distance from the earth is 65 light years. See also **Constellations**; and **Star**.

ACHILLES TENDON. In humans, the prominent tendon at the back of the ankle, extending from the muscle of the calf to the heel. Technically, it is the tendon which attaches the gastrocnemius and soleus muscles to the calcaneus or heel bone. The name derived from human anatomy is used in relation to other vertebrates.

ACHLORHYDRIA. Lack of hydrochloric acid in the digestive juices in the stomach. Hydrochloric acid helps digest food. The low pH of the normal stomach contents is a barrier to infection by various organisms and, where achlorhydria develops — particularly in malnutrition — it renders the patient more susceptible to infection, such as by *Vibrio cholerae* and *Giardia lamblia*. The condition is relatively common among people of about 50 years of age and older, affecting 15 to 20% of the population in this age group. The acid deficiency also occurs in about 30% of patients with adult onset-type of primary hypogamma-globulinemia. A well-balanced diet of easily digestible foods minimizes the discomforting effects of complete absence of hydrochloric acid in the stomach. The condition does not preclude full digestion of fats and proteins, the latter being attacked by intestinal and pancreatic enzymes. In rare cases, where diarrhea may result from achlorhydria, dilute hydrochloric acid may be administered by mouth. Where this causes an increase in discomfort or even pain, the use of dexamethasone or mucosal coating agents is preferred.

Commonly, achlorhydria may not be accompanied by other diseases, but in some cases there is a connection. For example, achlorhydria is an abnormality that sometimes occurs with severe iron deficiency. Histalog-fast achlorhydria, resulting from intrinsic factor deficiency in gastric juice, may be an indication of pernicious anemia. Hyperplastic polyps are often found in association with achlorhydria.

Excessive alcohol intake can also lead to achlorhydria and it is said that the resistance for cyanide poisoning of the Russian mystic, Rasputin, was attributable to that effect. The great amount of vodka that he consumed led to achlorhydria and thus the ingested potassium cyanide did not liberate lethal hydrocyanic gas, nor was the potassium salt absorbed through the stomach walls.

ACHONDRITES. A form of stony meteorites without chondri, and having textures similar to those of some terrestrial rocks. See **Meteoroids and Meteorites**.

ACHROMAT. A compound lens corrected so as to have the same focal length for two or more different wavelengths. Commonly, the F-and C-lines are the chosen wavelengths. See **Fraunhofer Lines**.

Achromats are used in optical microscopes for routine work, although they show some field curvature.

ACHROMATIC. Free from hue. Transmitting light without showing its constituent colors, or separating it into them. An achromatic color sometimes is referred to as gray.

Achromatic Combination. If reversed crown and flint prisms are made of such angle that the angles of dispersion between any two different wavelengths of light are alike but reversed in direction, then these two colors will not be separated and all colors lying between them will be separated little, if any, from each other. By using three kinds of glass, it is possible to bring three colors together. When the dispersions balance, the angles of deviation will, in general, not balance. This same principle is used in making achromatic lenses. Achromatic prisms have a maximum of deviation and a minimum of dispersion, whereas an Amici prism disperses the light with a minimum of deviation.

Achromatic Locus. Chromaticities that may be acceptable reference standards under circumstances of common occurrence are represented in a chromaticity diagram by points in a region that may be called the "achromatic locus." Any point within the achromatic locus, chosen as a reference point, may be called an "achromatic point." Such points have also been called "white points." However, the term "white point" is best used to specify the intersection of the various achromatic loci obtained under different conditions of adaptation.

Achromatic Stimulus. A visual stimulus that is capable of exciting a color sensation of no hue. In practice, an arbitrarily chosen chromaticity, such as that of the prevailing illumination.

ACHROMATOPSIA. Achromatopsia is a congenital eye defect that results in severe color blindness, poor detail vision, and photophobia, which is sensitivity to light. A hereditary condition, it occurs in 1 of 33,000 people in the United States, and it is more likely to occur in men than women. Congenital achromatopsia is not progressive, and it does not lead to blindness.

The cells that make up the retina are responsible for the ability to see detail, brightness, and color. There are two types of photoreceptor cells in the cornea: rods and cones. The rods specialize in work at low light levels, and the cones provide sharp vision, color, and contrast discrimination. People with achromatopsia have defective cone cells and must rely on their rod photoreceptors for vision.

In normal eyes, there are about six million cone photoreceptors, located mainly in the macula at the center of the retina. These cells are primarily responsible for sharp, straight-ahead vision, and also for the ability to distinguish colors. There are 100 million rod receptors, located mostly at the periphery of the retina. The rods are more sensitive to light than cones are, but rods are not able to differentiate among colors, nor can they perceive shades of gray, black, and white.

There are different variations in the severity of symptoms among individuals with achromatopsia. The rarest and most severe is called complete rod monochromatism, where there is a total lack of cone function. People with this disorder are extremely sensitive to light, even in normally lit rooms. They also have symptoms of poor visual acuity and nystagmus, which is involuntary movement of the eyes.

Other less severe variations of the disorder are known as incomplete rod monochromatism and blue cone monochromatism. The type depends on which cones are affected.

The main symptom of achromatopsia is photophobia, which is extreme sensitivity to light. The sun blinds people with achromatopsia, known asachromats when they, are outside. Some people are so sensitive to light that they are even uncomfortable indoors in a normally lit room. Because rods are sensitive to light but do not provide color or detail, people with achromatopsia are totally or partially color deficient, meaning they can see no or little color. They also have poor visual acuity and are limited in their ability to see at a distance.

Achromatopsia is hard to diagnose because the backs of the eyes appear normal when examined. The eye care professional bases the diagnosis on the patient's symptoms and on an electroretinogram.

Although there is no cure for achromatopsia, symptoms are manageable. Optical aids, sunglasses, and lowered illumination may be helpful to those with achromatopsia. In full sunlight or in very bright light indoors, achromats use very dark tinted lenses because their retinas do not possess the photoreceptors necessary for seeing well in such settings. Tinted contact lenses cut glare and allow achromats to see more clearly. Low vision rehabilitation also may be helpful.

ACID-BASE REGULATION (Blood). The hydrogen ion concentration of the blood is maintained at a constant level of pH 7.4 by a complex system of physico-chemical processes, involving, among others, neutralization, buffering, and excretion by the lungs and kidneys. This topic is sometimes referred to as *acid-base metabolism*. The clinical importance of acids and bases in life processes derives from several fundamental factors. (1) Most chemical reactions within the body take place in water solutions. The type and rate of such reactions is seriously affected by acid-base concentrations, of which pH is one indication. (2) Hydrogen ions are mobile charged particles and the distribution of such ions as sodium, potassium, and chloride in the cell environment are ultimately affected by hydrogen

ion concentration (pH). (3) It also has been established that hydrogen ion concentration influences the three-dimensional configurations of proteins. Protein conformational changes affect the biochemical activity of proteins and thus can affect normal protein function. For example, enzymes, a particular class of proteins, exhibit optimal activity within a narrow range of pH. Most physiological activities, and especially muscular exercise, are accompanied by the production of acid, to neutralize which, a substantial alkali reserve, mainly in the form of bicarbonate, is maintained in the plasma, and so long as the ratio of carbon dioxide to bicarbonate remains constant, the hydrogen ion concentration of the blood does not alter. Any non-volatile acid, such as lactic or phosphoric, entering the blood reacts with the bicarbonate of the alkali reserve to form carbon dioxide, which is volatile, and which combines with hemoglobin by which it is transported to the lungs and eliminated by the processes of respiration. It will also be evident from this that no acid stronger than carbon dioxide can exist in the blood. The foregoing neutralizing and buffering effects of bicarbonate and hemoglobin are short-term effects; to insure final elimination of excess acid or alkali, certain vital reactions come into play. The rate and depth of respiration are governed by the level of carbon dioxide in the blood, through the action of the respiratory center in the brain; by this means the pulmonary ventilation rate is continually adjusted to secure adequate elimination of carbon dioxide. In the kidneys two mechanisms operate; ammonia is formed, whereby acidic substances in process of excretion are neutralized, setting free basic ions such as sodium to return to the blood to help maintain the alkali reserve. Where there is a tendency toward development of increased acidity in the blood, the kidneys are able selectively to re-absorb sodium bicarbonate from the urine being excreted, and to release into it acid sodium phosphate; where there is a tendency toward alkalemia, alkaline sodium phosphate is excreted, the hydrogen ions thus liberated are re-absorbed to restore the diminishing hydrogen ion concentration. See also **Achlorhydria**; **Acidosis**; **Alkalosis**; **Blood**; **pH (Hydrogen ion concentration)**; and **Potassium and Sodium (In Biological Systems)**.

ACID DEPOSITION. The accumulation of an acidic chemical from the atmosphere to the surface of the earth, or to plants and structures at the surface.

Acids have high concentrations of hydrogen ions when dissolved in water, indicated by a pH less than 7. Acids can corrode metals, dissolve some types of rocks such as limestone, injure plants, and exacerbate some conditions in humans and animals. Acid deposition can occur in two forms: 1) wet deposition including acid rain, acid snow, acid hail, acid dew, acid frost, and acid fog; and 2) dry deposition including fallout of heavy particles, gravitational settling of lighter particles, and interception by and reaction with plant surfaces. Sometimes all forms of acid deposition are loosely called acid rain, although literally acid rain refers only to the liquid form. Ambient carbon dioxide, always present in the air, dissolves in cloud drops and raindrops creating carbonic acid with pH $\approx$ 5.6. Because this is a normal occurrence in the atmosphere, rain is defined to be acid rain only when it has pH $<$ 5.6. However, even in remote areas, there are sufficient sulfate, nitrate, ammonia, or soil cations (calcium or magnesium that are typically associated with carbonates) to cause "clean" atmospheric water to have pH in the range of 4.5–5.5. Polluted regions typically have pH in the range of 3–4, with values as low as 2–3. The chemicals that cause the greatest acid-deposition problems are oxides of sulfur (abbreviated as SO_x) and oxides of nitrogen (NO_x), which can react in the presence of atmospheric oxidants and water (e.g., clouds, fog and precipitation) to become sulfuric acid and nitric acid, respectively. These strong acids have an affinity for water, allowing droplets to grow hygroscopically in the atmosphere to produce haze or smog, even at relative humidities as low as 60% to 70%. See also **Acid Rain**.

AMS

ACIDIC SOLVENT. A solvent which is strongly protogenic, i.e., which has a strong tendency to donate protons and little tendency to accept them. Liquid hydrogen chloride and hydrogen fluoride are acidic solvents, and in them even such normally strong acids as nitric acid do not exhibit acidic properties, since there are no molecules that can accept protons; but, on the contrary, behave to some extent as bases by accepting protons yielded by the dissociation of the HCl or the HF. See **Acids and Bases**.

ACIDIMETRY. An analytical method for determining the quantity of acid in a given sample by titration against a standard solution of a base, or, more broadly, a method of analysis by titration where the end point is recognized by a change in pH (hydrogen ion concentration). See also **Analysis (Chemical)**; **pH (Hydrogen Ion Concentration**; **Titration (Potentiometric)**; and **Titration (Thermometric)**.

ACIDITY. The amount of acid present, expressed for a solution either as the molecular concentration of acid, in terms of normality, molality, etc., or the ionic concentration (hydrogen ions or protons) in terms of pH (the logarithm of the reciprocal of the hydrogen ion concentration). The acidity of a base is the number of molecules of monoatomic acid which one molecule of the base can neutralize. See **Acids and Bases**.

ACID NUMBER. A term used in the analysis of fats or waxes to designate the number of milligrams of potassium hydroxide required to neutralize the free fatty acids in 1 gram of substance. The determination is performed by titrating an alcoholic solution of the wax or fat with tenth or half-normal alkali, using phenolphthalein as indicator.

ACIDOSIS. A condition of excess acidity (or depletion of alkali) in the body, in which acids are absorbed or formed in excess of their elimination, thus increasing the hydrogen ion concentration of the blood, exceeding the normal limit of 7.4. The acidity-alkalinity ratio in body tissue normally is delicately controlled by several mechanisms, notably the regulation of carbon dioxide-oxygen transfer in the lungs, the presence of buffer compounds in the blood, and the numerous sensing areas that are a part of the central nervous system. Normally, acidic materials are produced in excess in the body, this excess being neutralized by the presence of free alkaline elements, such as sodium occurring in plasma. The combination of sodium with excess acids produces carbon dioxide which is exhaled. Acidosis may result from: (1) severe exercise, leading to increased carbon dioxide content of the blood, (2) sleep, especially under narcosis, where the elimination of carbon dioxide is depressed, (3) heart failure, where there is diminished ventilation of carbon dioxide through the lungs, (4) diabetes and starvation, in which organic acids, such as β-hydroxybutyric and acetoacetic acids, accumulate, (5) kidney failure, in which the damaged kidneys cannot excrete acid radicals, and (6) severe diarrhea, in which there is loss of alkaline substances. Nausea, vomiting, and weakness sometimes may accompany acidosis. See also **Acid-Base Regulation (Blood)**; **Blood**; **Kidney and Urinary Tract**; and **Potassium and Sodium (In Biological Systems)**.

ACID RAIN. Acid rain can be simply described as rain that is more acidic than normal. Acid rain is a complicated problem. Caused by air pollution, acid rain's spread and damage involve weather, chemistry, soil, and the life cycles of plants and animals on the land and in the water.

Scientists have discovered that air pollution from the burning of fossil fuels is the major cause of acid rain. Acidic deposition, or acid rain, as it is commonly known, occurs when emissions of sulfur dioxide (SO_2) and oxides of nitrogen (NO_X) react in the atmosphere with water, oxygen, and oxidants to form various acidic compounds. This mixture forms a mild solution of sulfuric acid and nitric acid. Sunlight increases the rate of most of these reactions.

These compounds then fall to the earth in either wet form (such as rain, snow, and fog or dry form (such as gas and particles). About half of the acidity in the atmosphere falls back to earth through dry deposition as gases and dry particles. The wind blows these acidic particles and gases onto buildings, cars, homes, and trees. In some instances, these gases and particles can eat away the things on which they settle. Dry deposited gases and particles are sometimes washed from trees and other surfaces by rain. When that happens, the runoff water adds those acids to the acid rain, making the combination more acidic than the falling rain alone. The combination of acid rain plus dry deposited acid is called *acid deposition*. See **Acid Deposition**, which is discussed in more detail later in this entry. Prevailing winds transport the compounds, sometimes hundreds of miles, across state and national borders.

Electric utility plants account for about 70 percent of annual SO_2 emissions and 30 percent of NO_X emissions in the United States. Mobile

sources (transportation) also contribute significantly to NO_X emissions. Overall, over 20 million tons of SO_2 and NO_X are emitted into the atmosphere each year.

Acid rain causes acidification of lakes and streams and contributes to damage of trees at high elevations (for example, red spruce trees above 2,000 feet in elevation). In addition, acid rain accelerates the decay of building materials and paints, including irreplaceable buildings, statues, and sculptures that are part of our nation's cultural heritage. Prior to falling to the earth, SO_2 and NO_X gases and their particulate matter derivatives, sulfates and nitrates, contribute to visibility degradation and impact public health.

Implementation of the Acid Rain Program under the 1990 Clean Air Act Amendments will confer significant benefits on the nation. By reducing SO_2 and NO_X, many acidified lakes and streams will improve substantially so that they can once again support fish life. Visibility will improve, allowing for increased enjoyment of scenic vistas across our country, particularly in National Parks. Stress to the forests that populate the ridges of mountains from Maine to Georgia will be reduced. Deterioration of historic buildings and monuments will be slowed. Finally, reductions in SO_2 and NO_X will reduce sulfates, nitrates, and ground level ozone (smog), leading to improvements in public health.

Surface Waters

Acid rain primarily affects sensitive bodies of water, that is, those that rest atop soil with a limited ability to neutralize acidic compounds (called "buffering capacity"). Many lakes and streams examined in a National Surface Water Survey (NSWS) suffer from chronic acidity, a condition in which water has a constant low (acidic) pH level. The survey investigated the effects of acidic deposition in over 1,000 lakes larger than 10 acres and in thousands of miles of streams believed to be sensitive to acidification. Of the lakes and streams surveyed in the NSWS, acid rain has been determined to cause acidity in 75 percent of the acidic lakes and about 50 percent of the acidic streams. Several regions in the U.S. were identified as containing many of the surface waters sensitive to acidification. They include, but are not limited to, the Adirondacks, the mid-Appalachian highlands, the upper Midwest, and the high elevation West.

In some sensitive lakes and streams, acidification has completely eradicated fish species, such as the brook trout, leaving these bodies of water barren. In fact, hundreds of the lakes in the Adirondacks surveyed in the NSWS have acidity levels indicative of chemical conditions unsuitable for the survival of sensitive fish species.

Emissions from U.S. sources also contribute to acidic deposition in eastern Canada, where the soil is very similar to the soil of the Adirondack Mountains, and the lakes are consequently extremely vulnerable to chronic acidification problems. The Canadian government has estimated that 14,000 lakes in eastern Canada are acidic.

Streams flowing over soil with low buffering capacity are equally as susceptible to damage from acid rain as lakes are. Approximately 580 of the streams in the Mid-Atlantic Coastal Plain are acidic primarily due to acidic deposition. The New Jersey Pine Barrens area endures the highest rate of acidic streams in the nation with over 90 percent of the streams acidic. Over 1,350 of the streams in the Mid-Atlantic Highlands (mid-Appalachia) are acidic, primarily due to acidic deposition. Many streams in that area have already experienced trout losses due to the rising acidity.

Acidification is also a problem in surface water populations that were not surveyed in federal research projects. For example, although lakes smaller than 10 acres were not included in the NSWS, there are from one to four times as many of these small lakes as there are larger lakes. In the Adirondacks, the percentage of acidic lakes is significantly higher when it includes smaller lakes (26 percent) than when it includes only the target size lakes (14 percent).

The acidification problem in both the United States and Canada grows in magnitude if "episodic acidification" (brief periods of low pH levels from snowmelt or heavy downpours) is taken into account. Lakes and streams throughout the United States, including high-elevation western lakes, are sensitive to episodic acidification. In the Mid-Appalachians, the Mid-Atlantic Coastal Plain, and the Adirondack Mountains, many additional lakes and streams become temporarily acidic during storms and snowmelt. Episodic acidification can cause large-scale "fish kills."

For example, approximately 70 percent of sensitive lakes in the Adirondacks are at risk of episodic acidification. This amount is over three times the amount of chronically acidic lakes. In the mid-Appalachians, approximately 30 percent of sensitive streams are likely to become acidic during an episode. This level is seven times the number of chronically acidic streams in that area.

Acid rain control will produce significant benefits in terms of lowered surface water acidity. If acidic deposition levels were to remain constant over the next 50 years (the time frame used for projection models), the acidification rate of lakes in the Adirondacks that are larger than 10 acres would rise by 50 percent or more. Scientists predict, however, that the decrease in SO_2 emissions required by the Acid Rain Program will significantly reduce acidification due to atmospheric sulfur. Without the reductions in SO_2 emissions, the proportions of aquatic systems in sensitive ecosystems that are acidic would remain high or dramatically worsen.

The impact of nitrogen on surface waters is also critical. Nitrogen plays a significant role in episodic acidification and new research recognizes the importance of nitrogen in long-term chronic acidification as well. Furthermore, the adverse impact of atmospheric nitrogen deposition on estuaries and other large bodies of water may be significant. For example, 30 to 40 percent of the nitrogen in the Chesapeake Bay comes from atmospheric deposition. Nitrogen is an important factor in causing eutrophication (oxygen depletion) of water bodies.

Forests

Acid rain has been implicated in contributing to forest degradation, especially in high-elevation spruce trees that populate the ridges of the Appalachian Mountains from Maine to Georgia, including national park areas such as the Shenandoah and Great Smoky Mountain national parks. Acidic deposition seems to impair the trees' growth in several ways; for example, acidic cloud water at high elevations may increase the susceptibility of the red spruce to winter injury.

There also is a concern about the impact of acid rain on forest soils. There is good reason to believe that long-term changes in the chemistry of some sensitive soils may have already occurred as a result of acid rain. As acid rain moves through the soils, it can strip away vital plant nutrients through chemical reactions, thus posing a potential threat to future forest productivity.

Visibility

Sulfur dioxide emissions lead to the formation of sulfate particles in the atmosphere. Sulfate particles account for more than 50 percent of the visibility reduction in the eastern part of the United States, affecting our enjoyment of national parks, such as the Shenandoah and the Great Smoky Mountains. The Acid Rain Program is expected to improve the visual range in the eastern U.S. by 30 percent. Based on a study of the value national park visitors place on visibility, the visual range improvements expected at national parks of the eastern United States due to the Acid Rain Program's SO_2 reductions will be worth a billion dollars by the year 2010. In the western part of the United States, nitrogen and carbon also play roles, but sulfur has been implicated as an important source of visibility impairment in many of the Colorado River Plateau national parks, including the Grand Canyon, Canyonlands, and Bryce Canyon.

Materials

Acid rain and the dry deposition of acidic particles are known to contribute to the corrosion of metals and deterioration of stone and paint on buildings, cultural objects, and cars. The corrosion seriously depreciates the objects' value to society. Dry deposition of acidic compounds can also dirty buildings and other structures, leading to increased maintenance costs. To reduce damage to automotive paint caused by acid rain and acidic dry deposition, some manufacturers use acid-resistant paints, at an average cost of $5 for each new vehicle (or a total of $61 million per year for all new cars and trucks sold in the U.S.) The Acid Rain Program will reduce damage to materials by limiting SO_2 emissions. The benefits of the Acid Rain Program are measured, in part, by the costs now paid to repair or prevent damage — the costs of repairing buildings, using acid-resistant paints on new vehicles, plus the value that society places on the details of a statue lost forever to acid rain.

Health

Based on health concerns, SO_2 has historically been regulated under the Clean Air Act. Sulfur dioxide interacts in the atmosphere to form sulfate aerosols, which may be transported long distances through the air. Most sulfate aerosols are particles that can be inhaled. In the eastern United

States, sulfate aerosols make up about 25 percent of the inhalable particles. According to recent studies at Harvard and New York Universities, higher levels of sulfate aerosols are associated with increased morbidity (sickness) and mortality from lung disorders, such as asthma and bronchitis. By lowering sulfate aerosol levels, the Acid Rain Program will reduce the incidence and the severity of asthma and bronchitis. When fully implemented by the year 2010, the public health benefits of the Acid Rain Program will be significant, due to decreased mortality, hospital admissions, and emergency-room visits.

Decreases in nitrogen oxide emissions are also expected to have positive health effects by reducing the nitrate component of inhalable particulates and reducing the nitrogen oxides available to react with volatile organic compounds (VOCs) and form ozone. Ozone impacts on human health include a number of morbidity and mortality risks associated with lung disorders.

Automotive Coatings

Since about 1990, reports of damage to automotive coatings have increased. The reported damage typically occurs on horizontal surfaces and appears as irregularly shaped, permanently etched areas. The damage can best be detected under fluorescent lamps, can be most easily observed on dark colored vehicles, and appears to occur after evaporation of a moisture droplet. In addition, some evidence suggests damage occurs most frequently on freshly painted vehicles. Usually the damage is permanent; once it has occurred, the only solution is to repaint.

The general consensus within the auto industry is that the damage is caused by some form of environmental fallout. "Environmental fallout," a term widely used in the auto and coatings industries, refers to damage caused by air pollution (e.g., acid rain), decaying insects, bird droppings, pollen, and tree sap. The results of laboratory experiments and at least one field study have demonstrated that acid rain can scar automotive coatings. Furthermore, chemical analyses of the damaged areas of some exposed test panels showed elevated levels of sulfate, implicating acid rain.

The popular term "acid rain" refers to both wet and dry deposition of acidic pollutants that may damage material surfaces, including auto finishes. These pollutants, which are released when coal and other fossil fuels are burned react with water vapor and oxidants in the atmosphere and are chemically transformed into sulfuric and nitric acids. The acidic compounds then may fall to earth as rain, snow, fog, or may join dry particles and fall as dry deposition. Automotive coatings may be damaged by all forms of acid rain, including dry deposition, especially when dry acidic deposition is mixed with dew or rain. However, it has been difficult to quantify the specific contribution of acid rain to paint finish damage relative to damage caused by other forms of environmental fallout, by the improper application of paint or by deficient paint formulations. According to coating experts, trained specialists can differentiate between the various forms of damage, but the best way of determining the cause of chemically induced damage is to conduct a detailed, chemical analysis of the damaged area.

Because evaporation of acidic moisture appears to be a key element in the damage, any steps taken to eliminate its occurrence on freshly painted vehicles may alleviate the problem. The steps include frequent washing followed by hand drying, covering the vehicle during precipitation events, and use of one of the protective coatings currently on the market that claim to protect the original finish. (However, data on the performance of these coatings are not yet sufficient.)

The auto and coatings industries are fully aware of the potential damage and are actively pursuing the development of coatings that are more resistant to environmental fallout, including acid rain. The problem is not a universal one — it does not affect all coatings or all vehicles even in geographic areas known to be subject to acid rain, which suggests that technology exists to protect against this damage. Until that technology is implemented to protect all vehicles or until acid deposition is adequately reduced, frequent washing and drying and covering the vehicle appear to be the best methods to minimize acid rain damage.

Acid Deposition

Sulfur and nitrogen oxides are emitted into the atmosphere primarily from the burning of fossil fuels. These emissions react in the atmosphere to form compounds that are transported long distances and are subsequently deposited in the form of pollutants such as particulate matter (sulfates and nitrates), SO_2, NO_2, nitric acid and when reacted with volatile organic compounds (VOCs) form ozone. The effects of atmospheric deposition include acidification of lakes and streams, nutrient enrichment of coastal waters and large river basins, soil nutrient depletion and decline of sensitive forests, agricultural crop damage, and impacts on ecosystem biodiversity. Toxic pollutants and metals also can be transported and deposited through atmospheric processes.

Both local and long-range emission sources contribute to atmospheric deposition. Total atmospheric deposition is determined using both wet and dry deposition measurements. Although the term "acid rain" is widely recognized, the dry deposition portion ranges from 20 to 60 percent of total deposition.

The United States Environmental Protection agency (EPA) is required by several Congressional and other mandates to assess the effectiveness of air pollution control efforts. These mandates include Title IX of the Clean Air Act Amendments (CAAA), the National Acid Precipitation Assessment Program (NAPAP), the Government Performance and Results Act, and the U.S. Canada Air Quality Agreement. One measure of effectiveness of these efforts is whether sustained reductions in the amount of atmospheric deposition over broad geographic regions are occurring. However, changes in the atmosphere happen very slowly and trends are often obscured by the wide variability of measurements and climate. Many years of continuous and consistent data are required to overcome this variability, making long-term monitoring networks especially critical for characterizing deposition levels and identifying relationships among emissions, atmospheric loadings, and effects on human health and the environment.

For wet and dry deposition, these studies typically include measurement of concentration levels of key chemical components as well as precipitation amounts. For dry deposition, analyses also must include meteorological measurements that are used to estimate rate of the actual deposition, or "flux." Data representing total deposition loadings (e.g., total sulfate or nitrate) are what many environmental scientists use for integrated ecological assessments. See **Acid Deposition**.

Primary Atmospheric Deposition Monitoring Networks

The National Atmospheric Deposition Program (NADP) and the Clean Air Status and Trends Network (CASTNET), described in detail below, were developed to monitor wet and dry acid deposition, respectively. Monitoring site locations are predominantly rural by design to assess the relationship between regional pollution and changes in regional patterns in deposition. CASTNET also includes measurements of rural ozone and the chemical constituents of $PM_{2.5}$. Rural monitoring sites of NADP and CASTNET provide data where sensitive ecosystems are located and provide insight into natural background levels of pollutants where urban influences are minimal. These data provide needed information to scientists and policy analysts to study and evaluate numerous environmental effects, particularly those caused by regional sources of emissions for which long-range transport plays an important role. Measurements from these networks are also important for understanding non-ecological impacts of air pollution such as visibility impairment and damage to materials, particularly those of cultural and historical importance.

National Atmospheric Deposition Network

The NADP was initiated in the late 1970s as a cooperative program between federal and state agencies, universities, electric utilities, and other industries to determine geographical patterns and trends in precipitation chemistry in the United States. Collection of weekly wet deposition samples began in 1978. The size of the NADP Network grew rapidly in the early 1980s when the major research effort by the NAPAP called for characterization of acid deposition levels. At that time, the network became known as the NADP/NTN (National Trends Network). By the mid-1980s, the NADP had grown to nearly 200 sites, where it stands today, as the longest running national deposition monitoring network.

The NADP analyzes the constituents important in precipitation chemistry, including those affecting rainfall acidity and those that may have ecological effects. The Network measures sulfate, nitrate, hydrogen ion (measure of acidity), ammonia, chloride, and base cations (calcium, magnesium, potassium). To ensure comparability of results, laboratory analyses for all samples are conducted by the NADP's Central Analytical Lab at the Illinois State Water Survey. A new subnetwork of the NADP, the Mercury Deposition Network (MDN) measures mercury in precipitation.

Clean Air Status and Trends Network

The CASTNET provides atmospheric data on the dry deposition component of total acid deposition, ground-level ozone, and other forms of atmospheric pollution. CASTNET is considered the nation's primary source for atmospheric data to estimate dry acidic deposition and to provide data on rural ozone levels. Used in conjunction with other national monitoring networks, CASTNET is used to determine the effectiveness of national emission control programs. Established in 1987, CASTNET now comprises over 70 monitoring stations across the United States. The longest data records are primarily at eastern sites. The majority of the monitoring stations are operated by EPA's Office of Air and Radiation; however, approximately 20 stations are operated by the National Park Service in cooperation with EPA.

Each CASTNET dry deposition station measures:

- weekly average atmospheric concentrations of sulfate, nitrate, ammonium, sulfur dioxide, and nitric acid.
- hourly concentrations of ambient ozone levels.
- meteorological conditions required for calculating dry deposition rates.

Dry deposition rates are calculated using atmospheric concentrations, meteorological data, and information on land use, vegetation, and surface conditions. CASTNET complements the database complied by NADP. Because of the interdependence of wet and dry deposition, NADP wet deposition data are collected at all CASTNET sites. Together, these two long-term databases provide the necessary data to estimate trends and spatial patterns in total atmospheric deposition. National Oceanic and Atmospheric Administration (NOAA) also operates a smaller dry deposition network called Atmospheric Integrated Assessment Monitoring Network (AIRMoN) focused on addressing research issues specifically related to dry deposition measurement.

Ozone Data Collection Network

Ozone data collected by CASTNET are complementary to the larger ozone data sets gathered by the State and Local Air Monitoring Stations (SLAMS) and National Air Monitoring Stations (NAMS) networks. Most air-quality samples at SLAMS/NAMS sites are located in urban areas, while CASTNET sites are in rural locations. Hourly ozone measurements are taken at each of the 50 sites operated by EPA. Data from these sites provide information to help characterize ozone transport issues and ozone exposure levels.

Integrated Monitoring, and AIRMoN

The Atmospheric Integrated Research Monitoring Network is an atmospheric component to the overall national integrated monitoring initiative that is currently evolving. AIRMoN is a relatively new program, constructed by combining and building upon pre-existing specialized wet deposition and dry deposition monitoring networks, and with two specific goals:

1. *To provide regular and timely reports on the atmospheric consequences of emission reductions, as imposed under the Clean Air Act Amendments*.

2. *To provide quantified information required to extend these observations of atmospheric effects to atmospheric deposition, both wet and dry*.

AIRMoN has two principal components: wet and dry deposition. All variables are measured in a manner that is designed to detect and properly attribute the benefits of emissions controls mandated under the Clean Air Act Amendments of 1990, and to reveal the actual deposition that occurred without fear of chemical (or other) contamination. It should be emphasized that conventional monitoring programs rely on statistical methods to extract small signals from imperfect and noisy data records. AIRMoN is designed to take a new step, that will remove much of the noise by integrating modern forecast technology into the monitoring process.

ARL presently focuses its research attention on:

- the measurement of precipitation chemistry with fine time resolution (AIRMoN-wet),
- the development of systems for measuring deposition, both wet and dry,
- the measurement of dry deposition using micrometeorological methods (AIRMoN-dry),
- the development of techniques for assessing air-surface exchange in areas (such as specific watersheds) where intensive studies are not feasible, and
- the extension of local measurements and knowledge to describe a real average exchange in numerical models.

Clean Air Act

The overall goal is to achieve significant environmental and public health benefits through reductions in emissions of sulfur dioxide (SO_2) and nitrogen oxides (NO_X), the primary causes of acid rain. To achieve this goal at the lowest cost to society, the program employs both traditional and innovative, market-based approaches for controlling air pollution. In addition, the program encourages energy efficiency and pollution prevention.

Title IV of the Clean Air Act Amendments of 1990 calls for a 10 million ton reduction in annual emissions of sulfur dioxide (SO_2) in the United States by the year 2010, which represents an approximately 40 percent reduction in anthropogenic emissions from 1980 levels. Implementation of Title IV is referred to as the Acid Rain Program; the primary motivation for this section of the Clean Air Act Amendments is to reduce acid precipitation and dry deposition. To achieve these reductions, the law requires a two-phase tightening of the restrictions placed on fossil-fuel-fired power plants.

The Act also calls for a 2 million ton reduction in NO_X emissions by the year 2000. A significant portion of this reduction will be achieved by coal-fired utility boilers that will be required to install low NO_X burner technologies and to meet new emissions standards.

Phase I began in 1995 and affects 263 units at 110 mostly coal-burning electric utility plants located in 21 eastern and midwestern states. An additional 182 units joined Phase I of the program as substitution or compensating units, bringing the total of Phase I affected units to 445. Emissions data indicate that 1995 SO_2 emissions at these units nationwide were reduced by almost 40% below their required level.

Phase II, which begins in the year 2000, tightens the annual emissions limits imposed on these large, higher emitting plants and also sets restrictions on smaller, cleaner plants fired by coal, oil, and gas, encompassing over 2,000 units in all. The program affects existing utility units serving generators with an output capacity of greater than 25 megawatts and all new utility units.

ACIDS AND BASES. The conventional definition of an acid is that it is an electrolyte that furnishes protons, i.e., hydrogen ions, H^+. An acid is sour to the taste and usually quite corrosive. A base is an electrolyte that furnishes hydroxyl ions, OH^-. A base is bitter to the taste and also

usually quite corrosive. These definitions were formulated in terms of water solutions and, consequently, do not embrace situations where some ionizing medium other than water may be involved. In the definition of Lowry and Brønsted, an acid is a proton donor and a base is a proton acceptor. Acid-base theory is described later.

Acidification is the operation of creating an excess of hydrogen ions, normally involving the addition of an acid to a neutral or alkaline solution until a pH below 7 is achieved, thus indicating an excess of hydrogen ions. In *neutralization*, a balance between hydrogen and hydroxyl ions is effected. An acid solution may be neutralized by the addition of a base; and vice versa. The products of neutralization are a salt and water.

Some of the inorganic acids, such as hydrochloric acid, HCl, nitric acid, HNO_3, and sulfuric acid, H_2SO_4, are very-high-tonnage products and are considered very important chemical raw materials. The most common inorganic bases (or alkalis) include sodium hydroxide, NaOH, and potassium hydroxide, KOH, and also are high-tonnage materials, particularly NaOH.

Several classes of organic substances are classified as acids, notably the carboxylic acids, the amino acids, and the nucleic acids. These and the previously mentioned materials are described elsewhere in this volume.

Principal theories of acids and bases have included: (1) Arrhenius-Ostwald theory, which was proposed soon after the concept of the *ionization* of chemical substances in aqueous solutions was generally accepted. (2) Much later (1923), J.N. Brønsted defined an acid as a source of protons and a base is an acceptor of protons. (3) T.M. Lowry, working in the same time frame as Brønsted, developed a similar concept and, over the years, the concept has been referred to in the literature as the *Lowry-Brønsted theory*. It will be noted that this theory altered the definition of an acid very little, continuing to emphasize the role of the hydrogen ion. However, the definition of a base was extended beyond the role of the hydroxyl ion to include a wide variety of uncharged species, such as ammonia and the amines. (4) In 1938, G.N. Lewis further broadened the definition of Lowry-Brønsted. Lewis defined an acid as anything that can attach itself to something with an unshared pair of electrons. The broad definition of Lewis creates some difficulties when one attempts to categorize Lewis acids and bases. R.G. Pearson (1963) suggested two main categories — hard and soft acids as well as hard and soft bases. These are described in more detail by Long and Boyd (1983). (5) In 1939, M. Usanovich proposed still another theory called the *positive-negative theory*, also developed in detail by Long and Boyd.

In terms of the definition that an acid is a proton donor and a base is a proton acceptor, hydrochloric acid, water, and ammonia (NH_3) are acids in the reactions

$$HCl \rightleftharpoons H^+ + Cl^-$$
$$H_2O \rightleftharpoons H^+ + OH^-$$
$$NH_3 \rightleftharpoons H^+ + NH_2^-$$

Note that this definition is different in at least two major respects from the conventional definition of an acid as a substance dissociating to give H^+ in water. The Lowry-Brønsted definition states that for every acid there be a "conjugate" base, and vice versa. Thus, in the examples cited above, Cl^-, OH^-, and NH^--are the conjugate bases of HCl, H_2O, and NH_3.

Furthermore, since the equations given above should more properly be written

$$HCl + H_2O \rightleftharpoons H_3O^+ + Cl^-$$
$$H_2O + H_2O \rightleftharpoons H_3O^+ + OH^-$$
$$NH_3 + H_2O \rightleftharpoons H_3O^+ + NH_2^-$$

It can be seen that every acid-base reaction involving transfer of a proton will involve two conjugate acid-base pairs, e.g., in the last equation NH_3 and H_3O^+ are the acids and NH_2^- and H_2O the respective conjugate bases. On the other hand, in the reaction

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-$$

H_2O and NH_4^- are the acids and NH_3 and OH^- the bases. In other reactions, e.g.,

Base$_1$		*Acid*$_2$		*Acid*$_1$		*Base*$_2$
$C_2H_3O_2^-$	+	H_2O	$\rightleftharpoons$	$HC_2H_3O_2$	+	OH^-
HCO_3^-	+	HCO_3^-	$\rightleftharpoons$	H_2CO_3	+	CO_3^{-2}
$N_2H_5^+$	+	$N_2H_5^+$	$\rightleftharpoons$	$N_2H_6^{+2}$	+	N_2H_4
H_2O	+	$Cr(H_2O)_6^{+3}$	$\rightleftharpoons$	N_3O^+	+	$Cr(H_2O)_5OH^{2+}$

the conjugate acids and bases are as indicated. The theory is not limited to the aqueous solution; for example, the following reactions can be considered in exactly the same light:

Base$_1$	*Acid*$_2$	*Acid*$_1$	*Base*$_2$
NH_3	+ HCl	$\rightleftharpoons$ NH_4^+	+ Cl^-
CH_3CO_2H	+ HF	$\rightleftharpoons$ $CH_3CO_2H_2^+$	+ F^-
HF	+ $HClO_4$	$\rightleftharpoons$ H_2F^+	+ ClO_4^-
$(CH_3)_2O$	+ HI	$\rightleftharpoons$ $(CH_3)_2OH^+$	+ I^-
C_6H_6	+ HSO_3F	$\rightleftharpoons$ $C_6H_7^+$	+ SO_3F^-

Acids may be classified according to their charge or lack of it. Thus, in the reactions cited above, there are "molecular" acids and bases, such as HCl, H_2CO_3, $HClO_4$, etc., and N_2H_4, $(CH_3)_2O$, C_6H_6, etc., and also cationic acids and bases, such as H_3O^+, $N_2H_5^+$, $N_2H_6^{2+}$, NH_4^+, $(CH_3)_2OH^+$, etc., as well as anionic acids and bases, such as HCO_3^-, Cl^-, NH_2^-, NH_3^{-2} etc. In a more general definition, Lewis calls a base any substance with a free pair of electrons that it is capable of sharing with an electron pair acceptor, which is called an acid. For example, in the reaction:

$$(C_2H_5)_2O: + BF_3 \longrightarrow (C_2H_5)_2O{:}BF_3$$

the ethyl ether molecule is called a base, the boron trifluroide, an acid. The complex is called a *Lewis salt*, or *addition compound*.

Acids are classified as monobasic, dibasic, tribasic, polybasic, etc., according to the number (one, two, three, several, etc.) of hydrogen atoms, replaceable by bases, contained in a molecule. They are further classified as (1) organic, when the molecule contains carbon; (1a) carboxylic, when the proton is from a — COOH group; (2) normal, if they are derived from phosphorus or arsenic, and contain three hydroxyl groups: (3) ortho, meta, or para, according to the location of the carboxyl group in relation to another substituent in a cyclic compound; or (4) ortho, meta, or pyro, according to their composition.

Superacids. Although mentioned in the literature as early as 1927, superacids were not investigated aggressively until the 1970s. Prior to the concept of superacids, scientists generally regarded the familiar mineral acids (HF, HNO_3, H_2SO_4, etc.) as the strongest acids attainable. Relatively recently, acidities up to 10^{12} times that of H_2SO_4 have been produced.

In very highly concentrated acid solutions, the commonly used measurement of pH is not applicable. See also **pH (Hydrogen Ion Concentration)**. Rather, the acidity must be related to the degree of transformation of a base with its conjugate acid. In the *Hammett acidity function*, developed by Hammett and Deyrup in 1932,

$$H_0 = pK_{BH^+} - \log \frac{BH^+}{B}$$

where $pkBH^+$ is the dissociation constant of the conjugate acid (BH^+), and BH^+/B is the ionization ratio, measurable by spectroscopic means (UV or NMR). In the Hammett acidity function, acidity is a logarithmic scale wherein H_2SO_4 (100%) has an H_0 of -11.9; and HF, an H_0 of -11.0.

As pointed out by Olah et al. (1979), "The acidity of a sulfuric acid solution can be increased by the addition of solutes that behave as acids in the system: $HA + H_2SO_4 \rightleftharpoons H_3SO_4^+ + A^-$. These solutes increase the concentration of the highly acidic H_3SO_4 cation just as the addition of an acid to water increases the concentration of the oxonium ion. H_3O^+. Fuming sulfuric acid (oleum) contains a series of such acids, the polysulfuric acids, the simplest of which is disulfuric acid, $H_2S_2O_7$, which ionizes as a moderately strong acid in sulfuric acid: $H_2S_2O_7 + H_2SO_4 \rightleftharpoons H_3SO_4^- + HS_2O_7^-$. Higher polysulfuric acids, such as $H_2S_3O_{10}$ and $H_2S_4O_{13}$, also behave as acids and appear somewhat stronger than $H_2S_2O_7$."

Hull and Conant in 1927 showed that weak organic bases (ketones and aldehydes) will form salts with perchloric acid in nonaqueous solvents. This results from the ability of perchloric acid in nonaqueous systems to protonate these weak bases. These early investigators called such a

system a superacid. Some authorities believe that any protic acid that is stronger than sulfuric acid (100%) should be typed as a superacid. Based upon this criterion, fluorosulfuric acid and trifluoro-methanesulfonic acid, among others, are so classified. Acidic oxides (silica and silica-alumina) have been used as solid acid catalysts for many years. Within the last few years, solid acid systems of considerably greater strength have been developed and can be classified as *solid superacids*.

Superacids have found a number of practical uses. Fluoroantimonic acid, sometimes called *Magic Acid*, is particularly effective in preparing stable, long-lived carbocations. Such substances are too reactive to exist as stable species in less acidic solvents. These acids permit the protonation of very weak bases. For example, superacids, such as Magic Acid, can protonate saturated hydrocarbons (alkanes) and thus can play an important role in the chemical transformation of hydrocarbons, including the processes of isomerization and alkylation. See also **Alkylation**; and **Isomerization**. Superacids also can play key roles in polymerization and in various organic syntheses involving dienone-phenol rearrangement, reduction, carbonylation, oxidation, among others. Superacids also play a role in inorganic chemistry, notably in the case of halogen cations and the cations of nonmetallic elements, such as sulfur, selenium, and tellurium.

Free Hydroxyl Radical. It is important to distinguish the free radical ·OH and the OH^- ion previously mentioned. The free radical is created by complex reactions of so-called "excited" oxygen with hydrogen as the result of exposure to solar ultraviolet light. The radical has been found to be an important factor in atmospheric and oceanic chemistry. The life span of the radical is but a second or two, during which time it reacts with numerous atmospheric pollutants in a scavenging (oxidizing) manner. For example, it reacts with carbon monoxide, as commonly encountered in atmospheric smog. It also reacts with sulfurous gases and with hydrocarbons, as may result from incomplete combustion processes or that have escaped into the atmosphere (because of their volatility) from various sources.

Because of the heavy workload placed upon the hydroxyl radical through such "cleansing" reactions in the atmosphere, some scientists are concerned that the atmospheric content of ·OH has diminished with increasing pollution, estimating the probable drop to be as much as 5–25% during the past three centuries since the start of the Industrial Revolution. Ironically, some of the very pollutants that are targets for reduction also are compounds from which the ·OH radical is produced and, as they are reduced, so will the concentration of ·OH be reduced. The fact that there is only one hydroxyl radical per trillion air molecules must not detract from its effectiveness as a scavenger.

Scientists at the Georgia Institute of Technology have devised a mass spectrometric means for testing the various theories pertaining to the chemistry of ·OH.

The probable importance of ·OH in the oceans also is being investigated. Researchers at Washington State University and the Brookhaven National Laboratory have confirmed the presence of ·OH in seawater and now are attempting to measure its content quantitatively and to determine the sources of its formation. Dissolved organic matter is one highly suspected source. Tentatively, it has been concluded (using a method called flash photolysis) that ·OH concentrations (as well as daughter radicals) range from 5 to 15 times higher in deep water than in open-ocean surface waters. This may indicate that ·OH may have some impact on biota residing in deep water and may enhance the secondary production of bacterial growth, particularly in "carbon limited" oligotrophic waters, in upwelling waters, and in regions with high ultraviolet radiation.

See also specific acids and bases, such as sulfuric acid and sodium hydroxide, in alphabetically arranged entries throughout this *Encyclopedia*.

ACIDULANTS AND ALKALIZERS (Foods). Well over 50 chemical additives are commonly used in food processing or as ingredients of final food products, essentially to control the pH (hydrogen ion concentration) of the process and/or product. An excess of hydrogen ions, as contributed by acid substances, produces a sour taste, whereas an excess of hydroxyl ions, as contributed by alkaline substances, creates a bitter taste. Soft drinks and instant fruit drinks, for example, owe their tart flavor to acidic substances, such as citric acid. Certain candies, chewing gums, jellies, jams, and salad dressings are among the many other products where a certain degree of tartness contributes to the overall taste and appeal.

Taste is only one of several qualities of a process or product that is affected by an excess of either of these ions. Some raw materials are naturally too acidic, others too alkaline — so that neutralizers must be added to adjust the pH within an acceptable range. In the dairy industry, for example, the acid in sour cream must be adjusted by the addition of alkaline compounds in order that satisfactory butter can be churned. Quite often, the pH may be difficult to adjust or to maintain after adjustment. Stability of pH can be accomplished by the addition of buffering agents that, within limits, effectively maintain the desired pH even when additional acid or alkali is added. For example, orange-flavored instant breakfast drink has just enough "bite" from the addition of potassium citrate (a buffering agent) to regulate the tart flavor imparted by another ingredient, citric acid. In some instances, the presence of acids or alkalies assists mechanical processing operations in food preparation. Acids, for example, make it easier to peel fruits and tubers. Alkaline solutions are widely used in removing hair from animal carcasses.

The pH values of various food substances cover a wide range. Plant tissues and fluids (about 5.2); animal tissues and fluids (about 7.0 to 7.5); lemon juice (2.0 to 2.2); acid fruits (3.0 to 4.5); fruit jellies (3.0 to 3.5).

Acidulants commonly used in food processing include: Acetic acid (glacial), citric acid, fumaric acid, glucono delta-lactone, hydrochloric acid, lactic acid, malic acid, phosphoric acid, potassium acid tartrate, sulfuric acid, and tartaric acid. Alkalies commonly used include: Ammonium bicarbonate, ammonium hydroxide, calcium carbonate, calcium oxide, magnesium carbonate, magnesium hydroxide, magnesium oxide, potassium bicarbonate, potassium carbonate, potassium hydroxide, sodium bicarbonate, sodium carbonate, sodium hydroxide, and sodium sesquicarbonate. Among the buffers and neutralizing agents favored are: Adipic acid, aluminum ammonium sulfate, ammonium phosphate (di- or monobasic), calcium citrate, calcium gluconate, sodium acid pyrophosphate, sodium phosphate (di-, mono-, and tri-basic), sodium pyrophosphate, and succinic acid.

See also **Buffer (Chemical)**; and **pH (Hydrogen Ion Concentration)**.

Functions of Acidulants. In the *baking industry*, acidulants and their salts control pH to inhibit spoilage by microbial actions to enhance the stability of foams (such as whipped egg albumin), to assist in leavening in order to achieve desired volume and flavoring, and to maximize the performance of artificial preservatives. A variety of the food acids previously mentioned is used. For example, citric acid traditionally has been favored by bakers for pie fillings. Baking powders (leavening agents) frequently will contain adipic acid, fumaric acid, and cream of tartar. Fumaric acid, in particular, has been the choice for leavening systems of cakes, pancakes, biscuits, waffles, crackers, cookies, and doughnuts. This acid also provides the desired characteristic flavor for sour rye bread — this eliminating fermentation of the dough to achieve desired flavor. Lactic acid and its salts sometimes are used as dough conditioners.

Acidulants are used in the *soft drink beverage industry* for producing a tart taste, improving flavor balance, modifying the "sweetness" provided by sugar and other sweeteners, extending shelf life by reducing pH value of final product, and improving the performance of antimicrobial agents. Specific acidulants preferred vary with the type of beverage — i.e. carbonated, non-carbonated, dry (reconstituted by addition of water), and low-calorie products.

In the production of *confections and gelatin desserts*, acidulants are used mainly for enhancing flavor, maintaining viscosity, and controlling gel formation. In confections, such as hard candies, acidulants are used to increase tartness and to enhance fruit flavors. Acidulants also contribute to the ease of manufacturing.

In *dairy products*, acidulants, in addition to achieving many of the foregoing functions, also help to process the products. As an example, adipic acid improves the texture and melting characteristics of processed cheese and cheese foods, where pH control is very important.

In *fruit and vegetable processing*, acidulants play somewhat different roles than previously described. These would include reducing process heating requirements through pH control, inactivating certain enzymes that reduce shelf life, and chelation of trace metals that may be present (through catalytic enzymatic oxidation). Citric acid is used widely in canned fruits, such as apricots, peaches, pears, cherries, applesauce, and grapes, to retain the firmness of the products during processing. The acid also provides a desirable tartness in the final products.

In the *processed meat field*, citric acid, along with oxidants, is used to prevent rancidity in frankfurters and sausages. Sodium citrate is used in processing livestock blood, which is used to manufacture some sausages and pet foods.

Acidulants and alkalizers, like other food additives, are controlled by regulatory bodies in most industrial nations. Some of the additives mentioned in this article are considered to be "Generally Regarded as Safe," having a GRAS classification. These include acetic, adipic, citric, glucone delta lactone, lactic, malic, phosphoric, and tartaric acids. Others are covered by the Code of Federal Registration (FDA) in the United States.

A very orderly and informative article (Dziezak 1990) is suggested as a source of detailed information on this topic.

ACLINIC LINE (or Dip Equator; Magnetic Equator). The line through those points on the earth's surface at which the magnetic inclination is zero. The aclinic line is a particular case of an isoclinic line. See **Isocline (Geodesy)**.

ACMITE-AEGERINE. Acmite is a comparatively rare rock-making mineral, usually found in nephelite syenites or other nephelite or leucite-bearing rocks, as phonolites. Chemically, it is a soda-iron silicate, and its name refers to its sharply pointed monoclinic crystals. Bluntly terminated crystals form the variety aegerine, named for Aegir, the Icelandic sea god.

Acmite has a hardness of 6 to 6.5, specific gravity 3.5, vitreous; color brown to greenish-black (aegerine), or red-brown to dark green and black (acmite). Acmite is synonymous with aegerine, but usually restricted to the long slender crystalline variety of brown color.

The original acmite locality is in Greenland. Norway, the former U.S.S.R., Kenya, India, and Mt. St. Hilaire, Quebec, Canada furnish fine specimens. United States localities are Magnet Cove, Arkansas, and Libby, Montana, where a variety carrying vanadium occurs.

ACNE VULGARIS. A chronic disorder of the pilosebaceous units and generally confined to the face, chest, and back. The primary lesions are horny plugs (blackheads), which later develop into pink papules, pustules, or nodules. Nodules are tender, acute, and localized collections of pus deep in the dermis. Large pustular lesions may develop and may break down adjacent tissue to form lakes of pus, sinuses, and characteristically pitted scars. Studies have shown that heredity is a major predisposing factor in the disease. It has been described by some authorities as polygenic (summed effects of many genes) and thus difficult to clearly delineate in terms of heredity.

Prior to puberty, the small pilosebaceous units are dormant. At puberty, these units enlarge and produce sebum by action of the sebaceous gland that converts circulating testosterone to 5a-dihydrostestosterone, which is the tissue androgen. See **Androgens**. Acne may occur when an excess of sebum is produced; or when the pilosebaceous follicular openings are too small to allow increased sebum flow; or when both conditions are present. The duration of acne vulgaris is highly variable and can persist well into the third decade of life. But, normally the disease peaks during the teen years and early twenties.

The microflora of acne lesions are usually those that are found in normal skin, including the anaerobic diphtheroid *Propionibacterium acne* and coagulase-negative staphylococci and micrococci. The yeast *Pityrosporum* usually colonizes the superficial layers of the lesions. Acneiform eruptions also may be caused by certain drugs, including phenytoin, isoniazid, lithium, and drugs containing halogens. Symptoms of steroid acne usually occur within two weeks after the commencement of systemic steroids. Papulopustular eruptions congregate on the upper chest, back, and arms. *Chloracne* is the result of occupational exposure to chlorinated hydrocarbons, tars, and cutting oils. Eruptions usually occur at points of contact with these foreign materials. *Acne rosacea* tends to affect middle-aged adults and occurs on the forehead, cheeks, nose, and chin, usually with the presence of facial flushing.

General measures to be taken for the care of acne include: (1) Thorough cleansing of the skin with soap and water at least once per day to remove dirt, sebum, and scales. Greasy cosmetics are to be avoided, but a water-base makeup may be used. (2) Frequent cleansing of scalp and hair with an antiseborrheic shampoo for removal of excess oil. (3) Hair should be worn off the face. (4) Physical tampering, such as squeezing of the lesions should be avoided. (5) Mild exposure to the sun's rays may be beneficial, but should be avoided in persons using topical retinoic acid. (6) The patient should attempt to relate types of food intake with any exacerbation of the acne — because some authorities believe there are dietary factors involved. However, formerly held associations of acne with certain taboos, such as chocolate, coffee, cola drinks, fatty foods, nuts, ice cream, and sweets, have not been proven. Some lotions and creams have been helpful in treating *noninflammatory* acne. These include sulfur (2 to 8%); resorcinol (1 to 4%); benzoyl peroxide (5 to 10%); and vitamin A acid (retinoic acid, 0.025 to 0.1%). The mode of action of these preparations is not fully understood, but generally they cause desquamation (peeling of scales) and cause papules and pustules to dry and peel. Sometimes, to inhibit the growth of *P. acne*, topical antibiotics, such as tetracycline, erythromycin, and clindamycin, are prescribed.

A breakthrough in the treatment of acne vulgaris occurred in the early 1980s, when a U.S. pharmaceutical firm introduced a powerful drug called *Accutane*, which, for carefully screened and qualified patients, often can accomplish rather remarkable results in returning the patient's complexion to one that is smooth and clear. Unfortunately, however, the drug must be highly restricted because of its teratogenic effects (birth defects and deformities) if administered to a pregnant patient or a patient contemplating pregnancy. The drug is for extreme cases of cystic acne and never in situations where pregnancy may be a factor.

ACOELA. An order of free-living flatworms in which the alimentary tract is without a cavity.

ACOELOMATA. Animals without a coelom. The term is applied especially to the flatworms, nemertine worms, and roundworms; these animals have attained a mesoderm, in which the body cavity develops but it remains a more or less continuous mass with small internal spaces if any.

ACOUSTIC MODE. A type of thermal vibration of a crystal lattice which, in the limit of long wavelengths, is equivalent to an acoustic wave traveling with nearly constant velocity as if through an elastic continuum. At high frequencies, approaching the Debye frequency, the phase velocity of the acoustic modes tends to decrease, owing to dispersion. See also **Crystal**.

ACOUSTIC PRINCIPLE OF SIMILARITY. For any acoustic system involving diffraction phenomena, it is possible to construct a new system on a different scale that will perform in similar fashion, provided that the wavelength of the sound is altered in the same ratio as the linear dimensions of the original system.

ACOUSTIC RAIN GAUGE. An instrument designed to determine rainfall over lakes and oceans. A hydrophone is used to sense the sound signatures for each drop size as rain strikes a water surface. Since each sound signature is unique, it is possible to invert the underwater sound field to estimate the drop-size distribution within the rain. Selected moments of the drop-size distribution yield rainfall rate, rainfall accumulation, and other rainfall properties.

ACOUSTIC SCINTILLATION. Irregular fluctuations in the received intensity of sounds propagated through the atmosphere from a source of uniform output. These variations are produced by the non-homogenous structure of the atmosphere along the path of sound. Turbulence and its concomitant variations in temperature and moisture are the chief causes of the nonhomogeneities that lead to sonic refraction, diffraction, and scattering responsible for acoustic scintillation.

ACOUSTICS. Broadly interpreted, *acoustics* is the science of sound and the technology which is associated with it.[1] Because of the complexity of the topic, it can be divided into two broad areas:

1. *Sound production and transmission* — an oscillation in pressure, stress, particle displacement, particle velocity, etc. in a medium with internal forces (for example, elastic, viscous), or the superposition of such propagated oscillations. For this definition, the terms *sound wave* or *elastic wave* or *phonon* are appropriate.

A sound wave is a longitudinal wave that consists of a sequence of pressure pulses or elastic displacements of air or other material (solid, liquid, or gas). A sound wave traveling in a gas is a sequence of compressions (dense gas) and rarefactions (less dense gas). Generally, of course, the gas in question is a mixture of nitrogen and oxygen (air). When sound travels in a solid, the sound wave is a traveling sequence of elastic compression and expansion waves. Similarly, in liquids, the sound wave is a traveling sequence of combined elastic deformation and compression waves. Propagation rate depends upon a number of variables, notably temperature, pressure, and the elastic properties of the medium. The currently accepted figure for the speed of sound in dry, open air under so-called standard conditions (0 °C; 1 atm) is 331.45 meters per second (741.43 miles per hour).[2] A *phonon* is an acoustic energy packet similar in concept to a photon (light) and a function of the frequency of vibration of a sound source. Phonons are contained in or form a sound wave.

2. *Sound as perceived* — a sound sensation evoked by the oscillations previously described. Not all sound waves, of course, will evoke an auditory sensation in human receptors. Sound frequencies are usually defined: *Audible*, 20 to 20,000 Hz (cps); *higher*, ultrasonic, 20,000 to $40{,}000 + H_2$; *lower*, infrasonic, below the audible range. For sound traveling in air at 1126 Hz, the wavelength is about one foot. In nature, the waves may be simple sinusoidal, complex, or explosive (shock), depending on the source. See also **Doppler Effect**.

Disciplines of Acoustics

Several disciplines fall within the realm of acoustics: (1) *Physical* acoustics; (2) *physiological* acoustics; (3) *psychological* acoustics, of which music is a major category, (4) *electroacoustics*, and (5) *architectural* acoustics.

Physical Acoustics

Physical acoustics deals with the fundamental *physics* and behavior of sound phenomena. Embraced are the properties and behavior of longitudinal waves of "infinitesimal" amplitude in solid, liquid, or gaseous media. These waves are propagated at the velocity of sound, or phase velocity, which is independent of frequency in a non-dissipating free medium. In such a case, the shape of a complex wave remains unchanged during its propagation, although its amplitude may change. When the velocity of sound, or phase velocity, becomes dependent on frequency, the shape of a complex wave changes during propagation and dispersion is said to occur. In such cases, groups of waves comprising a limited range of frequencies travel at a velocity known as the *group velocity*, which differs from the phase velocity. It is the group velocity that carries the energy of such complex waves.

Acoustic Waves. These waves are *dispersive*, (1) in a *free medium* in which viscosity, heat conduction, and molecular, thermal, or chemical relaxation cause an increase in phase velocity with frequency; (2) in a *confined medium*, in a capillary tube, for example, in which viscosity causes a decrease in phase velocity with frequency; (3) in a *confined medium* in non-dissipating tubes of increasing cross section, where the rate of change of cross-sectional area differs from the conical, i.e., different from proportionality to the square of the distance along the tube (examples of such tubes are the exponential and catenoidal horns, in which the phase velocity increases with decreasing frequency); (4) in non-dissipating cylindrical tubes with *flexible* walls; (5) in waves of *finite* amplitude, where the higher-frequency components have a higher phase velocity than the lower-frequency components, a transfer of energy occurring from the lower-frequency components to the higher-frequency components.

Physical acoustics studies the reflection, refraction, diffraction, and absorption of sound waves. Properties of wave motion, such as reinforcement and destructive interference, are studied. Such waves are accompanied by pressure and particle-velocity fluctuations detectable by the ear or by instruments capable of measuring the frequency instantaneous values, and mean intensity of these fluctuations.

In *geometrical acoustics*, a subcategory of physical acoustics, phenomena are studied where diffraction and interference are disregarded. Energies of direct and reflected waves are considered to add irrespective of relative phase, a condition that applies to incoherent (i.e., uncorrelated) waves.

Physiological Acoustics

This discipline deals with animal (principally human) hearing and its impairment, the voice mechanism, and the physical effects in general of sounds on living bodies. A number of specialties exist in this field. Medical professionals are concerned with the diagnosis, treatment, and prevention of illnesses and disorders of the human sound system, i.e., the ability not only to perceive (listen) sounds, but also with the means for creating (voice) sounds. The field also includes the design and application of means for improving both the hearing and voice systems — electronic hearing aids, improvements in telephony for creating clearer more audible messages, particularly for the hard of hearing, as well as speech training for the handicapped. Much more attention over the last several years has been devoted to reducing noise pollution and the dangers of long exposure of the human ear to adverse acoustical conditions in the workplace.

Human ears do not respond, in general, to frequencies outside the audio band (20–20,000 Hz), although small animals such as cats and bats do hear in the lower ultrasonic region. At one time called supersonics, the term *ultrasonic* is now preferred to distinguish this area of high-frequency sound propagation from the noise of supersonic aircraft, supersonic fluid flow (as encountered in industrial valves), and shock waves in fluids, which have to do with speeds higher than the speeds of sound.

The *strength* of a sound field is measured by its mean square pressure expressed as sound pressure level (L_p) in decibels. Decibels are logarithmic units defining the range of sound pressure levels (L_p) between the minimum audible value at 1000 Hz (4 dB[3] — the threshold of hearing) for the average pair of good young (high school age) ears and the maximum audible value of L_p at which effects other than hearing (such as tickling

[1] IEEE Society on Acoustics, Speech, and Signal Processing.

[2] Most scientists over several decades have accepted the figure given here. S.K. Wong (National Research Council of Canada) recalculated the speed of sound from the original formula suggested by Laplace over two centuries ago. The calculation produced the figure 741.07 mph — 0.05% less than the accepted speed figure. In a careful review of experiments conducted over many years, Wong found a margin of error as great or greater than that which can be ascribed to his theoretical calculation. Fortunately, for most scientific and engineering purposes, the currently accepted value serves well.

[3] 0 dB at 1000 Hz is defined in older work as the threshold of hearing.

in the ears — the threshold of *feeling*) begin to appear. This upper limit shows up at about 120 dB at 1000 Hz.

Higher values of L_p (e.g., 130 dB) begin to cause pain in the average ear, and values of 160 dB may well cause instantaneous physical damage (perforation) to the tympanic membrane. The minimum audible sound pressure, p_0, at 1000 Hz is internationally accepted as 0.0002 microbar rms (i.e., 0.0002 dyne/cm^2, rms), and the sound pressure level at any other rms value of sound pressure, p, irrespective of frequency, is given by $L_p = 20 \log_{10}(p/p_0)$ dB. The bel (seldom used) is simply equal to 10 decibels. The bel appears first used in connection with power loss in telephone lines and is named in honor of Alexander Graham Bell.

Other reference pressures, p_0 may be used in special applications, instead of 0.0002 microbar, so it is essential to specify the reference pressure when quoting values of L_P.

The *loudness* of a sound field is judged by the ear in the audio frequency range. Loudness judgments by groups of observers have established a *loudness level* scale. The loudness level (L_N) in phons is arbitrarily taken equal to the sound pressure level L_p in dB at the reference frequency of 1000 Hz over the range from the threshold of hearing to the threshold of feeling. Jury judgment of equality in loudness between test tones at different frequencies (f) and 1000 Hz reference tones of known sound pressure level (L_p) have established *equal loudness* contours (contours of constant L_N) in the $L_p - f$ plane.

These contours show in general a marked decrease in ear sensitivity to sounds at frequencies below about 200 Hz, and this decrease is much more pronounced in the lower loudness levels. For example, at 50 Hz the 4-phon contour has an L_p of about 43 dB, the 80-phon contour about 93 dB. At higher frequencies, the ear shows some 8-dB increase in sensitivity in the region around 3500 Hz, then a loss in sensitivity beyond about 6000 Hz. These characteristics of hearing are significant in the design of lecture and music halls, noise-control devices, and high-fidelity audio equipment.

Also based on jury judgments, a scale of *loudness*, N, (in sones) has been established for sounds (for pure tones and for broad band noise). On this scale, a given percentage change in sone value denotes an equal percentage change in the subjective loudness of the sound. The scale provides single numbers for judging the relative loudness of different acoustical environments, for evaluating the percentage reduction in noise due to various noise control measures, and for setting limits on permissible noise in factories, from motor vehicles, etc.

Loudness N is related to loudness level L_N in the range 40 to 100 phons by the equation $\log_{10} N = 0.03 L_N - 1.2$. A loudness of 1 sone corresponds to a loudness level of 40 phons and is typical of the low-level background noise in a quiet home.

Various methods are available for estimating loudness of complex sounds from their sound pressure levels in octave, half-octave, or third-octave bands. For traffic noises, readings on a standard sound level meter using the A-scale (which incorporates a frequency-weighting network approximating the variation of ear sensitivity with frequency to tones of 40-dB sound pressure level) appear to correlate reasonably well with jury judgments of vehicle loudness.

The *noisiness* of a broad-band noise is more related to the annoyance it causes than to its loudness. Thus, corresponding to the scale of sones created to measure loudness, a scale of *noys* has been developed as a measure of the noisiness of jet aircraft noise in particular. Noys give more importance to the high-frequency bands of noise and less importance to the low-frequency bands than do sones. Also, corresponding to the scale of loudness levels in phons, there has been established a scale of *perceived noise levels* in PN dB. Rules have been established for converting sound pressure level measured in octave bands, half-octave bands and third-octave bands into noys and then into PN dB. Although originally developed as a means for the assessment of the "noisiness" of jet aircraft flying over inhabited communities, the concept of noisiness is being applied to traffic and other broad-band noises. See also **Hearing and the Ear**.

Psychological Acoustics

This diverse discipline deals with the emotional and mental reactions of persons to various sounds. What sounds are acceptable to most people under various living conditions and what sounds are not? For what period of time can undesirable sounds be tolerated (aside from possible physical damage)? Over the years, various noise criteria have been developed that are related to the so-called preferred speech interference level PSIL. By definition, PSIL is the average of the sound pressure levels in decibels (L_p) in three octave frequency bands centered on 500 Hz, 1,000 Hz, and 2,000 Hz. The loudness level in phons (L_N) of a broadband noise (no outstanding pure tones) should not be over 22 phons (at the most, not over 30 phons) greater than the PSIL, in decibels, of the background noise.[4] Two noise control criteria (NC and NCA) are designed to fulfill these conditions for various sound fields, ranging from radio and television broadcasting studios, through bedrooms, offices, restaurants, sports arenas, and factories.

Musical Sounds. A major segment of psychological acoustics (although popularly considered more of an art than a science) is music. It is well accepted, of course, that music exerts numerous emotional responses. It is only within the last few decades that a number of researchers have investigated musical sounds from the standpoint of basic physics. A merger of electronics with sound, of course, commenced with radio, followed shortly by the extensive use of electronic equipment for amplifying and conditioning musical sounds at concerts and recording studios. Then, entered the interface between computer science and electronically composed and produced music — with the most recent impact being the digital reproduction of musical sounds on compact discs, where a laser beam serves as the equivalent of the pickup or stylus of a conventional record player.

A musical sound may be described as an aural sensation caused by the rapid periodic motion of a sonorous body. In contrast, noise is an aural sensation due to non-periodic motions. These observations, originally made by Helmholtz, may be modified slightly so that the frequencies of vibration of the body fall within the limits of hearing: 20 to 20,000 Hz. This definition is not clear-cut; there are some noises in the note of a harp (the twang) as well as a recognizable note in the squeak of a shoe. In other cases, it is even more difficult to make a distinction between music and noise. In some modern "electronic music," hisses and thumps are considered a part of the music. White noise is a complex sound whose frequency components are so closely spaced and so numerous that the sound ceases to have pitch. The loudness of these components is approximately the same over the whole audible range, and the noise has a hissing sound. Pink noise has its lower frequency components relatively louder than the high frequency components.

The attributes of musical sound and their subjective correlates are described briefly. The number of cycles per second, frequency, is a physical entity and may be measured objectively. Pitch, however, is a psychological phenomenon and needs a human subject to perceive it. In general, as the frequency of a sonorous body is raised, the pitch is higher. However, pitch and frequency do not bear a simple linear relationship. To show the relationship, a pitch scale can be constructed so that one note can be judged to be two times the pitch of another and so on. The unit of pitch is called the mel, and a pitch of 1,000 mels is arbitrarily assigned to a frequency of 1,000 Hz. In general, it is observed that the pitch is slightly less than the frequency at frequencies higher than 1,000 cycles, and slightly more than the frequency at frequencies less than 1,000 Hz. Pitch also depends on loudness. For a 200 cycle tone if the loudness is increased the pitch decreases, and the same happens for frequencies up to 1,000 Hz. Between 1,000 and 3,000 Hz pitch is relatively independent of loudness, while above 4,000 Hz, increasing the loudness raises the pitch. A rapid variation in pitch when the variation occurs at the rate of from two to five times per second is called vibrato. The pitch variation in mels may be large or small but the rate at which the pitch is varied is rarely greater than five times per second. Violinists produce vibrato by sliding their fingers back and forth a minute distance on a stopped string. A variation in loudness occurring at the rate of two to five times a second is called tremolo. Singers often produce a combination of tremolo and vibrato to give added color to their renditions.

Like frequency, intensity is a physical entity defined as the amount of sound energy passing through unit area per second in a direction perpendicular to the area. It is proportional to the square of the sound pressure, the latter being the rms pressure over and above the constant mean atmospheric pressure. Since sound pressure is proportional to the amplitude of a longitudinal sound wave and to the frequency of the wave, intensity is proportional to the square of the amplitude and the square of the frequency. Sound intensity is measured in watts per second per square

[4] A Phon is the unit of loudness level. Loudness level in phons is equal to the sound pressure level in decibels with reference to 0.0002 microbar of a pure tone of 1000 Hz, which a group of listeners judge to be equally loud.

centimeter and, since the ear is so sensitive to sound, a more usual unit is microwatt per second per square centimeter. By way of example, a soft speaking voice produces an intensity of .1 micromicrowatt/cm^2 sec, whereas 1,500 bass voices singing fortissimo at a distance 1 cm away produce 40 watts/cm^2 sec. Because of such large ranges of intensities, the decibel scale of intensity is normally used to designate intensity levels. An arbitrary level of 10^{-16} watts/cm^2 sec is taken as a standard for comparison at 1,000 Hz. This is very close to the threshold of audibility. At this frequency, other sound levels are compared by forming the logarithm of the ratio of the desired sound to this arbitrary one. Thus $\log I/10^{-16}$ is the number of bels a sound of intensity I has, compared to this level. Since this unit is inconveniently large, it has been subdivided into the decibel one-tenth its size; $10 \log I/10^{-16}$ equals the number of decibels (dB) the sound has. A few intensity decibel levels are listed:

	dB
Quiet whisper	10
Ordinary conversation	60
Noisy factory	90
Thunder (loud)	110
Pain threshold	120

While intensity levels can be measured physically, loudness levels are subjective and need human subjects for their evaluation. The unit of loudness is the phon, and an arbitrary level of 0 phons is the loudness of a 1,000-Hz note which has an intensity level of 0 dBB. Sounds of equal loudness, however, do not have the same intensity levels for different frequencies. From a series of experiments involving human subjects, Fletcher and Munson in 1933 constructed a set of equal loudness contours for different frequencies of pure tones. These show that for quiet sounds (a level of 5 phons) the intensity level at 1,000 cycles is about 5 dB lower than an equally loud sound at 2,000 cycles, for 30 cycles about 70 dB lower, and at 10,000 cycles about 20 dB lower. In general, as the intensity level increases, loudness levels tend to be more alike at all frequencies. This means that as a sound gets less intense at all frequencies, the ear tends to hear the higher and lower portions of sound less loudly than the middle portions. Some high fidelity systems incorporate circuitry that automatically boosts the high and low frequencies as the intensity level of the sound is decreased. This control is usually designated a loudness control.

That entity which enables a person to recognize the difference between equally loud tones of the same pitch coming from different musical instruments is called timbre, quality, or tone color. A simple fundamental law in acoustics states that the ear recognizes only those sounds due to simple harmonic motions as pure tones. A tuning fork of frequency f, when struck, causes the air to vibrate in a manner which is very nearly simple harmonic. The sound that is heard does, in fact, give the impression that it is simple and produces a pure tone of a single pitch. If one now strikes simultaneously a series of tuning forks having frequencies f (the fundamental), $2f$, $3f$, $4f$, $5f$, etc. (overtones), the pitch heard is the same as that of the single fork of frequency f except that the sound has a different quality. The quality of the sound of the series can be changed by altering the loudness of the individual forks from zero loudness to any given loudness. Another way to alter the tone quality is to vary the time it takes for a composite sound to grow and to decay. A slow growth of an envelope even though it contains the same frequencies makes for a different tone quality than one that has a rapid growth. The difference in quality between a b-flat saxophone and an oboe is almost entirely due to the difference in growth or decay time.

A fundamental theorem discovered by the mathematician Fourier states that any complicated periodic vibration may be analyzed into a set of components which has simple harmonic vibrations of single frequencies. If this method of analysis is applied to the composite tones of musical instruments, it is seen that these tones consist of a fundamental plus a series of overtones, the intensity of the overtones being different for instruments of differing timbre. Rise and decay times will also differ. The reverse of analysis is the synthesis of a musical sound. Helmholtz was able to synthesize sound by combining sets of oscillating tuning forks of various loudness to produce a single composite steady tone of a definite timbre. Modern synthesizers are more sophisticated. Electrical oscillators of the simple harmonic variety are combined electrically and then these electrical composite envelopes are electronically modified to produce differing rise and decay times. A transducer changes the electrical composite envelope into an acoustical one so that a sound of any desired timbre rise and decay time can be produced. An alternate way to produce similar effects is to use an oscillation known as the square wave. When this is analyzed by the method of Fourier, it is shown to consist of a fundamental plus the odd harmonics or overtones. Another kind of oscillator, a sawtooth wave, when analyzed, is shown to consist of the fundamental and all harmonics — even and odd. A square wave or a saw-tooth wave produced by an appropriate electrical oscillator can be passed through an electrical filter that can attenuate any range of frequencies of the original wave. This altered wave can later be transformed into the corresponding sound wave. In this way sounds having a desired rise and decay time, plus the required fundamental and overtone structure, can be made as desired.

Learning from Antique Instruments. In comparatively recent years, considerable interest has been shown by individuals and groups of scientists in the acoustics of early (17th and 18th century) musical instruments. The investigators use modern research tools and analytical techniques, but even with this new technology, there remains a considerable mystique as to how the early craftsmen achieved the exceptionally high sound quality of their instruments.

Hutchins (see *Additional Reading*) reports on the acoustics of violin plates. A worldwide but small organization (Catgut Acoustical Society) has used advanced scientific methods in the study of violins and other string instruments. Modern tests of the vibrational properties of the unassembled top and back plates of a violin reveal something of what the makers of violins do by intuition or "feel" in constructing consistently good violins. Complex mathematics involving the Chladni method of displaying the eigenmodes of a free (unattached) violin plate and the use of hologram interferometry for determining the vibrational patterns of violin plates were central to the study reported by Hutchins.

In a scholarly paper by Richardson, the manufacture of stringed musical instruments is assessed from the standpoint of acoustics and stresses that tone quality of a stringed instrument is intimately related to the modes of vibration of its *body*. Richardson discusses the vibrations of violins and guitars and shows how mode analysis and numerical modeling may lead to a quantitative understanding of the relationships between a musical instrument's construction and its tone quality. The author stresses that the greatest difficulties arising in violin making are associated with the mechanical properties of the wood used and that the maker must compensate for such variations by modifying the dimensions of the instrument parts. Although beyond the scope of this article, the results of holographic interferometry of a guitar are shown in Fig. 1 as being illustrative of the scientific sophistication that goes into such studies.

Over scores of years, there has been much speculation pertaining to selecting the right pieces of wood (for example, by Antonio Stradivari in his violin making, or by the Ruckers family in Antwerp, who produced harpsichords with such splendid sound). There is unconfirmed speculation that early instrument makers may have inspected the grain of wood to determine its density by viewing sunlight through thin sections. Tillmann Steckner, a contemporary harpsichord maker in London, Ontario, as of 1989, had not been able to test his speculation by utilizing an x-ray technique because, "No one has given me a Stradivari to take apart."

The acoustics of the harpsichord also have been intensely studied by other investigators. One of the most intriguing aspects of this instrument is the "swirling sound" of the instrument. This is not produced by a piano. E.L. Kottick et al. have employed Chladni patterns and computer models, as have other investigators. Although the details of the research are beyond the scope of this volume, the investigators reason that the energy of the vibrating strings account for little sound directly picked up by the ear; rather, this energy is passed to the instrument's soundboard by way of the bridge. The strings actually move only a comparatively few molecules of air. Acting as a selective filter, the bridge then permits only some of the frequencies to pass to the soundboard. The latter superimposes its own characteristics on the frequencies received. Some of these are suppressed; others are enhanced. Additional factors which affect the instrument's sound include structural members and the cavity, all of which interact with the soundboard. Still another factor that contributes to the characteristics perceived by the ear is a strong bass. The researchers suggest that this is a psycho-physiological phenomenon that can be likened to heterodyning, as encountered in electronics. See also **Heterodyne**.

Baroque instruments other than vibrating strings also have been studied in recent years. For example, Rossing reports on a study of the physics of kettledrums. Rossing notes that the vibrations of a violin string form a

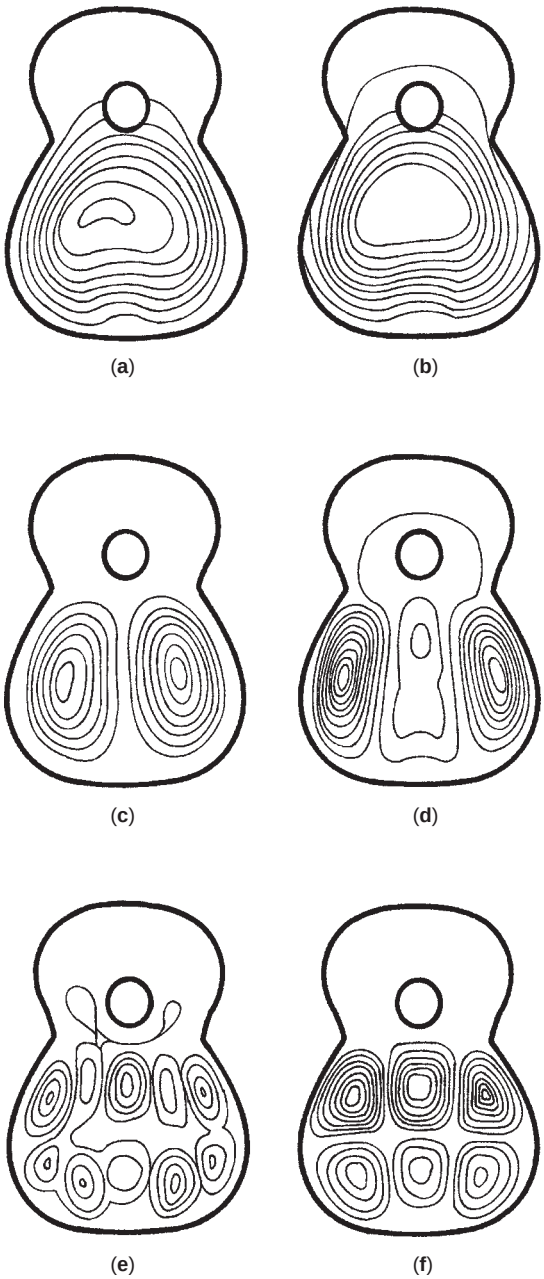

Fig. 1. To visualize the complex body vibration of musical instruments requires rather sophisticated research tools. Over many years of research, various methods have been devised to measure the fractional (tiny) displacements. These have included Chladni patterns and intricate capacitive probes. One method preferred today is *holographic interferometry*. This is the method used by Richardson at the University of Wales (Cardiff). Reasonable facsimiles of some of these are shown here. The modes of vibration of a guitar are visualized. Mode frequencies are (**a**) 106 Hz, (**b**) 2 to 16 Hz, (**c**) 268 Hz, (**d**) 553 Hz, (**e**) 1194 Hz, and (**f**) 509 Hz. The mode shapes and frequencies are unique to the instrument shown (guitar). The fringes shown are the result of interference between the multiple recorded by the hologram. As explained by researcher Richardson, the fringes form a contour map of the amplitude displacement of the plate (its *eigenfunction*). The system has a sensitivity on the order of 1 micrometer. These patterns reflect the construction of the particular instrument and are dependent upon such factors as the volume of the air cavity (depth of ribs and plate area) and the size of the round hole (called *F* hole in violin). The same principle that is used in bass-reflex loudspeakers, (i.e., a Helmholtz resonator) acts as the coupling between the plates and the air cavity.

harmonic series with a distinct pitch. The vibrations of an ideal membrane, in contrast, do not form such a series. How then can a kettledrum have a pitch? The Rossing paper partially answers this question. Future research will be directed toward better understanding other percussion instruments.

A revival of baroque music is putting greater emphasis on methods of singing and playing that satisfy criteria for historically correct performances. Many of the baroque musical instruments have been successfully constructed, the surviving antique originals having yielded many of their secrets. But not so, they report, for the baroque trumpet. The instrument today is not made as it was in the 17th and 18th Centuries; consequently, playing techniques have been compromised. The investigators explain in considerable detail their studies of the instrument and generally conclude that the problem of playing the baroque trumpet resides in the contrast of how the instrument was made a few centuries ago and how modern copies are made. They conclude that only by consistently applying historical principles to all three parts of the equation — the player, the mouthpiece, and the instrument — can one accurately revive the lost art of playing the baroque trumpet.

Mathematics and Musical Sound. Harmonics, the science of musical sounds, has been taught to serious students of music and the voice for at least two centuries, and in recent years this knowledge has been expanded markedly by applying computer technology to old principles. Ironically, as pointed out by Bracewell, the human ear essentially calculates in an instant a mathematical transform when it converts sound waves of pressure traveling through the atmosphere into a sound spectrum (i.e., a series of volumes at distinct pitches). The brain further processes this information into what is known as *perceived sound*. In the late 1700s, Baron Jean-Baptiste-Joseph Fourier, a French scientist and mathematician, developed a relatively complex mathematical method for analyzing complex *fluctuating* phenomena that relate not only to sound waves but also to such apparently unrelated areas as heat conduction. Although not universally applicable, Fourier found that a sum of sinusoidal (wave-like) functions would converge to correctly represent a discontinuous function. Thus, well established for scores of years as a useful mathematical method of analyzing sound, Fourier transforms now are being applied to the study of DNA's double helix, saw-tooth signals in electronics, and sunspot cycles, among others. See Fig. 2 and also **Fourier Transform**.

An example of how much more remains to be learned in the category of musical sounds is the paradoxical perception of pitch. A few decades ago, R.N. Shepard (AT&T Bell Laboratories) gathered an audience of listeners and repeatedly played an identical sequence of computer-generated tones that were moved up an octave. The panel, instead of commenting that there was undistorted repetition, curiously stated that there was a rise in pitch from one repetition to the next. Of course there was no external reason for this, and it was believed that some mechanism of human hearing was responsible for the phenomenon. Along similar lines, earlier professional musicians had hinted of the phenomenon. This puzzler of pitch perception has been termed the *tritone paradox*. Deutsch (Univ. of California, San Diego) and other researchers worldwide are exploring several hypotheses, including proposals that persons who speak different dialects of a language may perceive tonal patterns in strikingly different ways. This supports long-held speculation that the way people hear music is related in some way to their speech characteristics.

Research at MIT has included development of a computer program to assist students in writing programs that characterize certain composers. But, when students hear their programs played back, they find that such models fail in at least one critical way — i.e., some major composers, such as Bach and Vivaldi, have unique movements that to date have not yielded to formal, procedural organization.

In this present period of intensive research of musical sounds, the human voice has not been overlooked. A high-technology laboratory at the Oberlin (Ohio) College Conservatory of Music is providing new knowledge on the actions and performance of human vocal chords. Instrumentation used includes electronic displays of vibrato, oscillation, and tremolo. A sonograph-printer and spectrum analyzer are used to visualize a singer's resonance. An electro-laryngograph furnishes information on vocal chords, producing graphics of breathy singing. One researcher observes that the type of effort in biomechanics that has been made on behalf of sports should be duplicated in the study of vocal pedagogy. See also **Voice and Sound Production**.

The majority of scientists and musicians concerned with music research today recognize that much has been learned to date, but that the field is still in an experimental phase. Electronic music research emanates mainly from computer scientists who have strong personal interests in music. What they are seeking does not always match the interests of professional musicians, some of whom are seeking ways to enhance the effects of the human

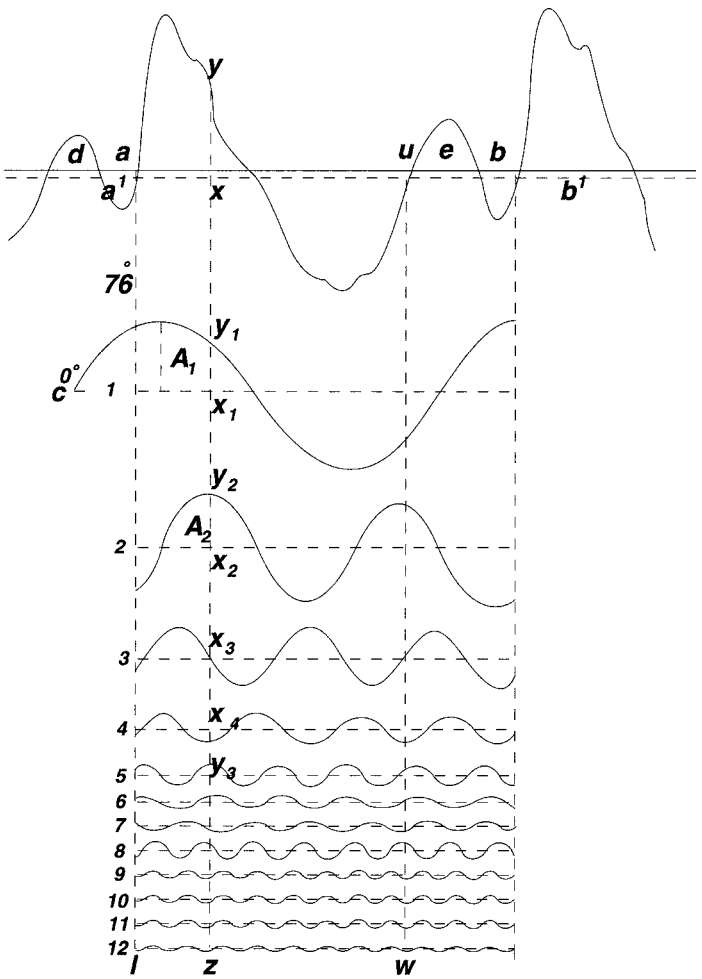

Fig. 2. Records of a complex sound and 12 of its components. Developed by Dayton C. Miller, a pioneer sound physicist (circa 1920).

performer. This would include searching for and using new musically related algorithms. Efforts along these lines are being made at the Institut de Recherche et Coordination Acoustique/Musique (Paris), where algorithms are being created so that a computer may track live music played by adjacent instruments. One researcher has observed that "finding the pitch" is a terribly difficult problem.

In another direction, some investigators are working on the concept of a "radio baton," which would incorporate a number of transmitters that would send signals to track the movement of the baton in 3-D. This tool, in essence, could then be used to direct a computer-simulated orchestra.

The goals of numerous and separate music research laboratories remain to be fully defined and coordinated. Thus, the experimental phase probably will continue into the foreseeable future.

Digital Reproduction of Musical Sounds. Although digitization has been used to enhance recordings of great artists from the past, the major thrust of digital reproduction is that of making superior recordings of contemporary performances. The first component of audio systems to use digital processing was the phonograph, but authorities are forecasting that every element of the sound system will ultimately employ digital technology. In the present and familiar *compact disc*, the sound is preserved as a series of microscopic pits and smooth areas. A laser beam, replacing the former stylus or pickup, serves as the playback device. In the older analog type of recording, the sound consists of a continuous variation of amplitude over time. Any deviations from linearity cause distortion on the waveform. All analog systems have some non-linearity. With analog systems, noise has been an ever-present problem. In addition to noise arising from the microphones used to make the recording, the recording medium per se is of a granular nature and introduces further noise. As pointed out by Monforte, the noise puts a lower limit on the resolving power of the storage medium. Bandwidth is another fundamental limitation of traditional recording devices. Monforte describes this as a limit on how quickly the system can respond to the rapid changes in amplitude that are characteristic of sounds.

Digitization of sound dates back to the 1920s when Bell Laboratories engaged in a project to find ways to overcome the limitations of analog recording. The waveform in a digital audio system is converted to a series of numbers, which become a description of the waveform. See Fig. 3.

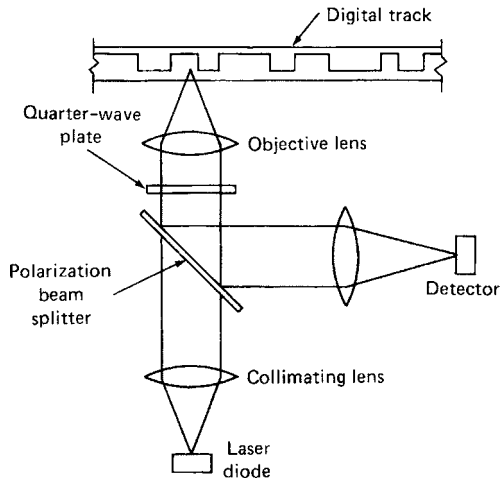

Fig. 3. Playback system used in connection with digitally recorded discs (*Compact Disc*). Light from a laser diode, shown at bottom of diagram, is passed through a collimating lens to alleviate any tendency for the beam to diverge. A polarized beam splitter divides the concentrated beam. Part of the beam is passed to the detector at right. The remaining portion of the beam passes through another filter that rotates the axis of polarization by 90 degrees. An objective lens focuses the beam on the disc surface (digital track) shown along top of diagram. Highly exaggerated bumps on the surface (about the size of the wavelength of incident light) scatter the light, preventing it from returning to the detector. Instantly, the detector senses the decline in beam intensity. These variations are read by the system as a string of binary digits (1's and 0's).

In digital recording, the familiar analog-to-digital (A/D) technique is used. In making this conversion, both amplitude and time must be incorporated into the digital signal. (A/D techniques have been used in the computer process control field for many years.) Reconstruction of the signal again follows earlier techniques used in other fields — the digital signal is fed to a digital-to-analog (D/A) converter. The resulting signal is a replica of the original waveform. The system is subject to two major sources of error — inadequate sampling and quantification.

Because of the very high density of stored data, the compact disc has nearly unlimited potential in electronic data processing. The compact disc was developed by the Philips Corporation of The Netherlands in cooperation with the Sony Corporation of Japan. The disc has a 500-megabyte capacity.

Beginning in the late 1980s, the motion picture industry turned to all-digital sound. Binary code, as compared with an analog signal on a plastic or magnetic tape, is not subject to deterioration. This is a very attractive advantage. Editing digital sound also can be simpler and less time consuming, contributing to lower cost. However, the initial switching of the film industry to all-digital technology represents a very large investment in equipment (optical storage, for example); in the meantime, the suppliers of analog sound equipment are improving their systems. Thus, the resistance to change is economic and coupled with institutional inertia. Digital recording has been gaining experience from use in shorter films and has been particularly adept for filling in special effects. Digital sound is particularly effective for recording background street noises, the clatter and rumbling of subway and rail cars, the slamming of doors, pouring liquids, and so on. Some experts still insist that, with exception of such special effects for enhancing realism, analog recording sounds the best. A larger number of experts consider the trend to digital as inevitable. However, still other experts claim that the recording method used should not be the major consideration, but that much more precise design attention should be given to improving the acoustics of theater buildings, as well as upgrading the theater's sound delivery system.

In an exceptionally interesting paper, Fletcher and Thwaites describe in detail the physics of the concert hall organ at the Sydney Opera House (Australia) which was completed in 1979. The Sydney organ, designed and built by Ronald Sharp, has some 10,500 pipes controlled by the mechanical action of five keyboards and a pedal board. The mechanical action, which regulates the flow of air into the pipes, is duplicated by an electric action that is under microprocessor control. The organ, therefore, can be operated by a magnetic tape on which an original performance has been digitally recorded.

Electroacoustics

This discipline is concerned with the principles by which electrical energy can be converted into acoustic energy and vice versa. Consider the familiar electro-dynamic transducer. A periodic electric current passing through a coil interacts with a steady radial magnetic flux causing the coil to vibrate. The coil in turn drives a diaphragm that radiates sound waves from one side. (The other side is usually enclosed to avoid cancellation of the acoustic output.) The entire process is *reversible* since sound waves striking the diaphragm set up a periodic variation in air pressure adjacent to the diaphragm causing it to vibrate. As the moving coil cuts the magnetic flux, an emf is generated which causes a current to flow when a load is connected to the coil terminals.

Many, but not all, types of transducer are similarly reversible. A reversible transducer may be made to perform sending and receiving functions successively in such a manner that an absolute sensitivity may be determined (*reciprocity* calibration).

The electro-dynamic transducer may further be classified as *passive*, since all of the energy appearing in the acoustic load is derived from the electrical input energy, and *linear*, in the sense that there is a substantially linear relationship between the input and output variables (electric current and acoustic pressure in the present case).

Irreversible Transducers. These depend on a variety of special effects of which the best known is (a) the variation of surface contact electrical resistance with pressure (carbon microphone). Other effects are (b) the variation of bulk resistance with elastic strain (piezoresistance), (c) variation of transistor parameters with strain, (d) cooling effect of periodic air movement (hot wire microphone), (e) pressure wave generated by an electrical spark, (f) dependence of air pressure on level of corona discharge (ionophone). See also **Microphone**.

Reversible Transducers. An important class of reversible transducer depends on relative movement of suitable components linked by an electric or magnetic field traversing a gap. Examples are (a) the electro-dynamic transducer already described; (b) electrostatic depending on the relative movement of charged condenser plates; (c) magnetic or variable reluctance depending on relative movement of magnetic poles in a magnetic circuit linked with a fixed coil.

Other *reversible transducers* are dependent on dimensional changes connected with the state of magnetic or electric polarization of certain crystalline materials (piezomagnetism and piezoelectricity). Since strain may be longitudinal or shear and since both strain and polarization are directional quantities, many possible relationships between strain and polarization exist. The behavior of an X-cut quartz disk may serve as an illustration. When such a disk is axially compressed, electric charges appear on the plane surfaces. Conversely, if a potential difference is established between the two surfaces, contraction or expansion occurs depending on the direction of the electric field. Other important single-crystal piezoelectric materials are ammonium dihydrogen phosphate (ADP) and Rochelle salt. During the past decade, polycrystalline ceramic materials based on barium titanate and lead zirconate titanate have replaced single-crystal materials in many applications. These materials are ferroelectric and, when prepolarized, exhibit piezoelectric behavior.

To date, only polycrystalline piezomagnetic materials (often termed magnetostrictive) have been found useful. Some are metals such as nickel and permendur. Others are ferrite ceramics [basic composition: $(NiO)(Fe_2O_3)$] which have such a high electrical resistivity that eddy current losses are negligible making lamination unnecessary.

Electromechanical Coupling. Transducer performance is closely connected with the tightness of coupling between mechanical and electrical aspects. Consider a piezoelectric disk which is compressed by putting in *mechanical energy* W_m. The appearance of surface charges shows that *electrical energy* W_e is stored in the self capacitance and is available when an external circuit is connected to suitable electrodes. The ratio W_e/W_m (electromechanical coupling coefficient) sets a limit to the efficiency for a given bandwidth (frequency range). The coefficient may reach 70% for lead zirconate titanate.

Transducer Design. Impedance matching is of primary importance in electroacoustics. It may be likened to the choice of gear ratio and wheel size in automobile design. Impedance matching is generally closely related to transducer parameters such as beam width of projected or received sound and frequency response, as well as efficiency. The many available matching technique include (a) Resonance, (b) horn systems (acoustic transformers), (c) lever systems (mechanical transformers). In the direct radiator electrodynamic loudspeaker, the diaphragm is made large enough to interact with the acoustic medium (air) and yet small enough in relation to the sound wavelength (at low frequencies, at least) to ensure uniform projection of sound over a wide angle. In the condenser loudspeaker, a large transducer area compensates for the weakness of electrostatic forces. In the underwater sonar project, slabs of piezoelectric ceramic may be sandwiched between metal plates to form a resonant device which radiates a narrow beam of sound with high efficiency over a narrow frequency range.

Beginning in 1970, much progress has been made toward refining an acoustic (voice) interface between people and computers. This topic is explored in the entry on **Telephony**; and **Voice and Sound Production**, among others. In the development of systems and components for various kinds of voice communications, it is necessary in the performance of various tests to isolate a chamber (*anechoic chamber*) as much as possible from ambient radiation, including sound and other electromagnetic radiation. A chamber of this type is shown in Fig. 4.

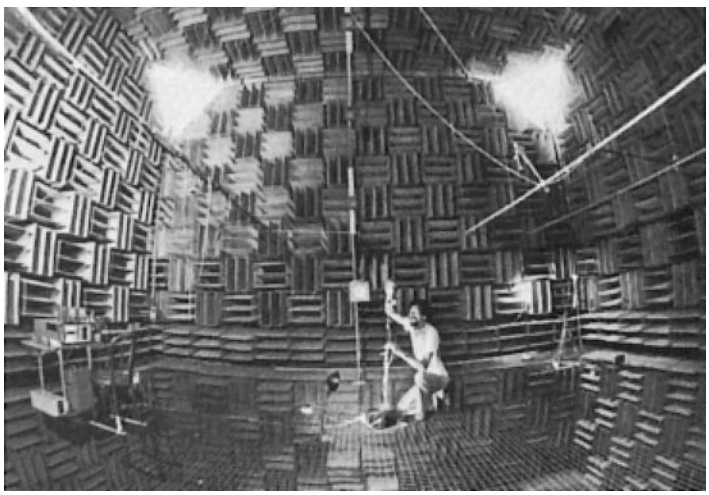

Fig. 4. Anechoic chamber, a superquiet space for testing acoustic components and systems. Adjustments on a directional microphone are being made in preparation for determining its directional characteristics. (*AT&T Bell Laboratories*.)

Microwave Acoustics. This field is concerned with the use of acoustic waves in solids for signal storage, amplification, and processing in the frequency range above 50 MHz. A piezoelectric transducer thin enough to operate in the fundamental mode at several hundred MHz can be formed by evaporating a thin film of piezoelectric material onto a suitable substrate or by forming a semiconductor *depletion layer* of the correct thickness. *Magnetoelastic transducers* have been formed of materials such as yttrium iron garnet (YIG) which operate in the resonance mode of the ferromagnetic spin system and generate longitudinal acoustic waves.

A sound-transmitting bar and a pair of transducers provide an effective and compact *delay line*. The interaction of free charges with elastic waves in piezoelectric materials can provide acoustic amplification, which can be achieved with a longitudinal electric field sufficient to establish a carrier drift velocity greater than the elastic wave velocity. *Traveling-wave amplifiers* with 40 dB gain and 10% bandwidth at 1 GHz for a one millimeter transmission path have been built with semiconductors.

The *interdigital transducer* is an array of parallel conducting strips with $\lambda/2$ spacing deposited on a piezoelectric substrate, such as lithium niobate, which provides efficient excitation of acoustic surface waves (Rayleigh waves). Surface waves generated in this fashion can be guided and selectively delayed by grooves and metallic film boundaries and can be

coupled in and out at many points along the path. Surface waves also can be amplified by drifting charge carriers in the substrate or in a semiconductor layer above the wave-carrying surface. These properties are compatible with integrated circuit techniques.

The *electret microphone* uses an electrostatic transducer in which a polarizing field is maintained by a quasi-permanent charge layer embedded in a thin plastic film. The electret transducer has very high electrical impedance and can be combined with an integrated field effect transistor (FET) amplifier. Complex array properties can be built into electret microphones. Examples include the second-order gradient (toroidal) microphone for conference use and a square array for acoustic holography.

The *parametric acoustic array* has provided a means for obtaining a narrow beam of low-frequency underwater sound, using a small primary transducer. Due to the non-linearity of the equations of fluid motion, a pair of highly collimated high-frequency sound beams can be made to act as a very large end-fire array, launching a directional sound beam at a comparatively low difference frequency. Since the liquid medium rapidly absorbs the primary beams, the array is *tapered*.

Intense coherent sound waves can be generated at several GHz by the electrostrictive processes that accompany the passage of intense laser beams through liquids and solids (stimulated Brillouin scattering).

Architectural Acoustics

In this field, scientists and engineers deal with the problems of distribution of beneficial sounds within buildings and with the exclusion of reduction of undesirable sounds. It has been known for many years that the mass and limpness of barriers, such as partitions, are highly important in providing high sound transmission loss. In auditoriums, reflective ceilings and reflective walls, combined with convex irregularities of random design, provide for reinforcement and diffusion of sound found so beneficial for speech and music. Reflecting surfaces, giving short time-delay reflections (about 20 ms or less), are particularly desirable in concert halls. Delays of 65 ms or more may result in echoes and speech unintelligibility.

Publications of specifications for environmental and architectural acoustics are obtainable from the American Society for Testing and Materials.

During the early 1990s, major advancements occurred in architectural acoustics. An example is a computer graphics program developed at Cornell University, in which a wireframe rendition of a symphony hall is constructed. As the first hall to be studied, the researchers selected the design of Boston Symphony Hall, which is famous for its superior acoustics. A simulated sound is created from center stage. Initially, this expands in the form of a simple sphere in bold colors on the screen. Reflections are then produced from the ceiling and balconies of the hall, but in subtler hues of color. As the signal dies out, only a few uncolored areas remain, thus identifying locations in the hall without sound. When designing a new hall or contemplating design improvements, a special wireframe representative of the geometry of the target hall can be made. One of the researchers on this project observes that each sound can be observed as it travels all over the hall and in steps of 1 ms, which is a finer resolution than what the human ear can perceive. With just a few instructions to the system, one can select the best from a series of possible hall design situations, such as the best ceiling slopes, balcony arrangements, ceiling and inside wall building materials, and so forth.

This technique may eliminate the need for constructing intricate physical models that normally use light waves instead of sound as the testing medium.

Automotive Acoustics

Traditionally, predicting noise in the passenger compartment of an automobile in the early design stage was considered unachievable. Acoustic analysis was simple — build a prototype vehicle, get in, listen, then try to calm the cacophony. This trial-and-error acoustic engineering created numerous problems, for once a noise was designed in, it was difficult and costly to eliminate it in the prototype or production models. Vehicle body structures are much like metal drums. Vibrations induced by the road, by the car's aerodynamic loadings, and by the power train all generate sound in much the same way as the vibrating skin of a drum.

Several years ago, General Motors (U.S.) developed a computer-based acoustic model by mapping out the complex dimensional geometry of the passenger vehicle interior. The model was a useful analytical tool because it could define booming frequencies and anticipate design problems. But the model did not provide sufficient information to identify which part of the structure created the noise, nor, more importantly, did it indicate what modifications would reduce the noise.

The next step was development of a system in which the acoustic model was coupled with a computer-aided structural model. The structural model could simulate vibration responses of body surfaces during actual vehicle operations. With a coupling equation, the structural model could be linked with the acoustic model to translate vibration data into the sound effects. The combined structural-acoustic model can identify noise paths, pinpointing the parts of the body structure that are likely to create noise and the percentage which various panels and modes contribute. The model can suggest structural modifications, such as redesigning a panel, early in the design stage to avoid costly add-on solutions that also may add weight to the vehicle. The new methodology has been verified by a comparison study between the structural-acoustic model's predictions and actual prototype vans driven over rough roads at the GM proving grounds. As shown by Fig. 5, the model accurately predicted both acoustic peaks and overall noise levels. A new systems approach to acoustic prediction and modification is shown in diagram form in Fig. 6.

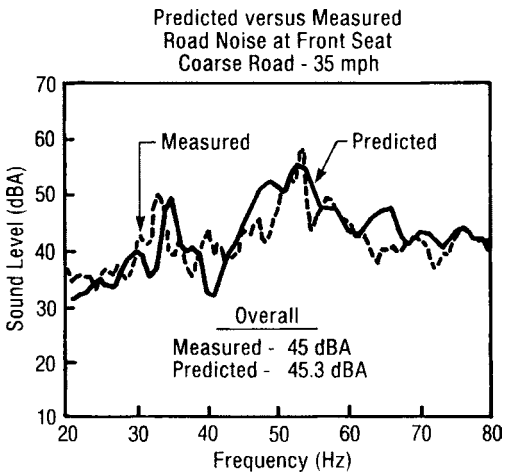

Fig. 5. Comparison of the acoustic computer model's predictions made in the laboratory versus actual measurements made on the proving ground. Tests were for a prototype van and show the close relationship between predictions and actual noise experience. (*General Motors Corp.*)

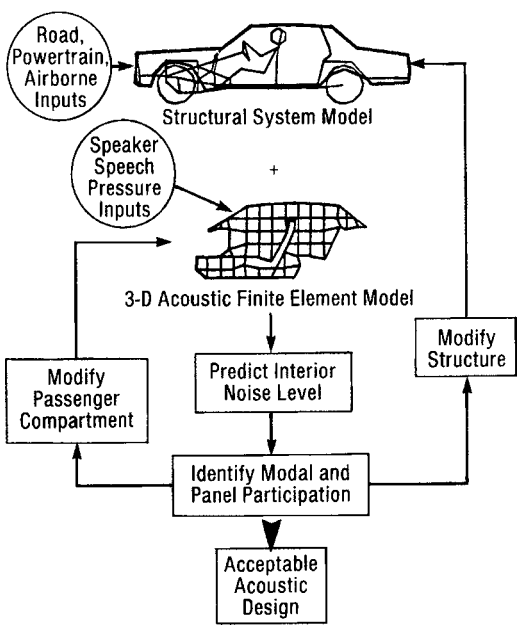

Fig. 6. Systems approach to acoustic prediction and modification for producing more acceptable vehicle designs during the earliest, pre-prototype stages in the development of a new vehicle. System predicts what parts of the car or van structure create noise and how this noise is transmitted. (*General Motors Corp.*)

Other Applications of Acoustic Phenomena

Ultrasound in Chemistry. Chemical reactions between two or more materials involve energy transfer. A reaction might (1) spontaneously generate energy (most often thermal), or (2) require the absorption of external energy to proceed partially or fully to completion. In the latter case, ultrasound frequently is an excellent source of external, additional energy. Generally, the application of acoustic energy to chemistry is termed *sonochemistry*.

Ultrasound in high-energy chemistry is particularly effective when one or more liquid reactants are involved. Mixtures of homogeneous liquids or slurries (liquid-solids systems) are good examples. The application of ultrasound normally is successful because of a phenomenon known as *acoustic cavitation*. See also **Cavitation**. The latter occurs when ultrasound creates bubbles in the reactant(s), which expand rapidly, followed by what is known as *implosive collapse*, during which localized spots of very high temperature (5000 °C; 9000 + °F) are created and accompanied by very high pressures (up to 500 atmospheres). This process occurs within a few microseconds, creating shock waves that travel at extremely high velocities, causing, in a liquid-solid slurry, for example, impacts (collisions) between particles. It is estimated that the strength of such energy releases could instantaneously melt most metals. In fact, ultrasound is commonly used to clean metal surfaces that are highly reactive, as well as for increasing the effectiveness of catalytic reactions.

Ultrasound, with certain materials, also can cause the emission of light. Known as *sonoluminescence*, this property was observed by Frenzel and Schultes (1934). Although not applied to practical advantage, it has been found in recent years to apply to nonaqueous as well as water components. Currently, sonoluminescence is considered to be a form of *chemiluminescence*. The relatively recent emergence of ultrasound's importance in chemistry is very well summarized in the Suslick (1990) reference listed.

Instrumentation and Testing. Acoustic emissions, particularly ultrasound, are widely and variously used for testing the properties of materials and for imaging (medical applications being just one example). In recent years, ultrasonic microscopy has evolved from a laboratory to an industrial inspection technique. The use of acoustic emissions for testing pressure vessels used in industry has been commonplace for many years. The use of ultrasonic nondestructive characterization of materials has been widely used for years. These and other applications are described in various parts of this *Encyclopedia*. Check alphabetical index.

ACOUSTIC SENSORS. Acoustic sensors may be understood to mean transducers, devices, or systems that generate, detect, or measure mechanical vibrations. These vibrations may be characterized in terms of frequency, bandwidth, information content, intensity, polarization, speed of propagation, and the rate at which they are attenuated. Mechanical vibrations or elastic waves interact with, influence, or are influenced by other elastic waves and also by other forms of energy (thermoacoustic or optoacoustic interactions), a material's elastic properties and stress, and metallurgical and chemical processes (ultrasonic welding, sonochemistry). Acoustic waves are influenced by gradients and inhomogeneities in, and by the motion of, the medium in which they are propagating (turbulent or particulate scattering, beam drift, Doppler shift), and by the boundaries of that medium, or boundary conditions. See also **Acoustics**.

Ultrasonic refers to elastic waves of frequency $f \geq 20$ kHz. Ultrasonic waves are thus vibrations at a frequency above human hearing. With respect to sensing and measurements, high frequency avoids interference from many audible, low-frequency noises due to wind, machinery, pumps, and vibration of large bodies. High frequency allows resolution of "the small" in both the temporal and spatial senses. Attenuation often imposes the upper limit on the maximum usable frequency. *Audible* frequencies, 16 Hz $< f <$ 20 kHz, are sometimes selected to overcome attenuation or to limit propagation to one mode in a plate. The parameter that is to be measured is called the *measurand*. See also **Untrasonics**.

The *sensor* may be a system that includes one or more transducers and the medium itself or an existing internal or bounding structure. The sensor system may also be a foreign sensor, intrusive, added to the existing process to make the required measurement. The four main measurands in process control are flow, pressure, temperature, and level. (To the extent that flow measurements include mass flow rate and flow profile, the rheological properties of fluids such as density and viscosity may be viewed as falling occasionally under the "flow" umbrella.) To sense these measurands by ultrasonic pulse techniques, one can measure propagation in the medium itself (e.g., speed of sound in air is proportional to the square root of the air's absolute temperature), or in a "sensor" that touches the medium. Rather than perturb the situation, one prefers to exploit an

existing structural element as the sensor, or as a reflector that bounds the sensed medium at a known location. A pipe wall or an entire section of pipe, for example, can sometimes be used as a temperature sensor, a fluid-density sensor, or an acoustic window that allows one to interrogate the fluid within the pipe noninvasively. The fluid then serves as its own "sensor." On the other hand, to avoid uncertainties attributed to variability in existing structural elements not expressly designed nor quality controlled for sensing, one may need to introduce a foreign sensor [or foreign reflector(s)] for measurement purposes. This invasive sensor is often a resonator or waveguide — some form of probe — in which propagation is a unique and repeatable function of the measurand in the medium. The invasive or "wetted" sensor may also consist of one or more transducers that are each acoustically isolated from the medium's boundary, and hence from one another if two transducers are used, so that the medium can be interrogated or listened to without interference from boundary-borne noises.

Acoustical waves are often selected as the means to measure a particular parameter. One example is measuring the distance to a moving web or sheet. The sound waves can accomplish this task without contacting the web. Ultrasound often gets the job done with no penetration of the boundary (e.g., clampon transducers) or with minimal disturbance of the measurand even when the boundary must be penetrated (e.g., wall-mounted transducers for an across-the-stack flow measurement). Another example is downward-looking "air sonar" to measure the level of liquids in a tank or solids in a bin. Process-control engineers may select acoustical waves to sense process measurands when they need

- noninvasive, noncontact, or minimally invasive measurement;
- high accuracy (measurands usually transformed to time or frequency measurements);
- reliability (no moving parts, in the usual sense);
- fast response (can be <1 ms);
- remote sensing, sometimes with no physical contact;
- average reading over an extended region;
- profile information (point by point, or small-path average);
- computer compatibility of time, frequency, or, say, 8-bit amplitude data;
- low cost, especially for multiplexed and/or mass-produced sensors;
- small size, small mass;
- avoidance of problem(s) associated with competing (nonultrasonic) technologies;
- data or results unobtainable any other way; and
- useful sensing of two or more parameters simultaneously, e.g., flow velocity and composition, density and viscosity, or flow velocity and density.

The seven basic elements in a typical active acoustical sensing system may be represented as [Electrical Energy Source]® [Electronic Transmitter]® [Electroacoustic Transmitting Transducer]® [Wave–Measurand Interaction Zone]® [Acoustoelectric Receiving Transducer]® [Electronic Receiver]® [Information Output]. These [items] or [functions] will become clear in relation to measuring specific measurands. An abbreviated representation of an active acoustical sensing system is [Transmit]® [Interact]® [Receive].

ACOUSTIC SOUNDING. 1. The technique of remote sensing in which an instrument sends acoustic waves vertically and receives reflections from atmospheric features such as inversions or turbulent layers. 2. A representation of the vertical profile of one or more of the state variables of a fluid body (typically the ocean or atmosphere) deduced from variations in reflected acoustic energy. 3. A particular measurement of depth of water below an instrument (either at the surface or at some moored depth) computed from the travel time of an acoustic pulse emitted by the acoustic sounder.

AMS

ACOUSTIC THERMOMETER. A device to measure air temperature based on the principle that the speed of sound varies as the square root of temperature. The most common application is in so-called *sonic anemometers*, where the time-of-flight of sound pulses between a pair of acoustic transducers is used to determine the speed of sound. This measurement is converted to temperature via the formula

$$c_s{}^2 = 403\ T(1 + 0.32\ e/P),$$

where c_s is the speed of sound, T the air temperature (K), e the partial pressure of atmospheric water vapor (mb), and P the atmospheric static pressure (mb).

See also **Sonic Anemometer**.

AMS

ACOUSTIC TOMOGRAPHY. A type of imaging technique in which information is collected from beams of acoustic radiations that have passed through an object, generally in the form representing a two-dimensional slice through the object.

In oceanography, acoustic tomography consists of an inverse technique that uses acoustic signals to sample the interior of the ocean. In this way, the temperature structure of the interior ocean can be reconstructed from acoustic signals in multiple vertical planes.

ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS). Since the first descriptions of AIDS in 1981, a global pandemic consisting of thousands of separate epidemics in communities around the globe has expanded rapidly, especially in developing countries where more than 90% of HIV-infected people live. Since the early 1980's, more that 40 million individuals have contracted HIV (Human Immunodeficiency Virus), the causative agent of AIDS, and almost 12 million have died. In 1997, 2.3 million people including 460,000 children succumbed to the disease despite the introduction of powerful therapies which are able to slow the course of, although not cure, the disease. Although the number of deaths and HIV-related hospitalizations has begun to decline in the United States and other economically advantaged nations where these expensive therapies are available, HIV continues to spread rapidly in sub-Saharan Africa and in Southeast Asia. Unprotected heterosexual sex accounts for most of HIV's spread in Sub-Saharan Africa and the problem is compounded by contamination of the blood supply, one quarter of which is not routinely screened for the AIDS virus. In Southeast Asia, India and Thailand dominate the picture as the epidemic continues to spread rapidly in populations suffering from a lack of educational and economic opportunities. Indeed social marginalization, including the low social status of women who in many cases lack the power to insist upon safe-sex practices, magnifies the risk throughout the developing countries as well as in population segments of the industrialized world.

HIV, the etiologic agent of AIDS, is a retrovirus (contains an enzyme reverse transcriptase allowing it to produce DNA copies of itself), its genetic material being RNA rather than DNA. Originally called human T-lymphotropic virus type lll/Lymphadenopathy-associated virus (HTLV-lll/LAV), a subcommittee of the International Committee for the Taxonomy of Viruses designated HIV as the appropriate nomenclature. In 1985, a second human retrovirus associated with AIDS was identified in West Africa, leading to the designation of HIV-1 for the original virus and HIV-2 for the West African form which has since been isolated from patients outside of West Africa. Biological differences in virulence and progression to AIDS between the two viruses have been described although patterns of transmission are similar. It is now known that both forms of HIV are highly mutable viruses that regularly undergo major changes in their genetic expression and surface characteristics. HIV is transmitted between humans by three principal routes: horizontally through sexual contact or parenteral inoculation of virus-containing blood and other body fluids and vertically from an infected mother to her offspring. In many respects, the epidemiology of AIDS appears to resemble that of hepatitis B. In developed countries, male-to-male sexual contact has accounted for the preponderance of sexual transmission, whereas in developing countries most sexual transmission of HIV is by heterosexual contact and in urban areas is frequently associated with prostitution. The relatively recent increase in heterosexual transmission in developed countries has occurred particularly among sexual partners of infected IV drug abusers and is facilitated by high-risk sexual activity associated with alcohol and illicit drug abuse. Transmission of HIV in transfused blood products is a particularly efficient route with up to 90% of recipients of infected blood becoming infected. However, the institution of serologic screening of donated blood has greatly reduced the incidence of transfusion-associated HIV infection in the countries that have implemented successful programs. The AIDS virus is a relatively fragile virus, and there is no evidence that it can be transmitted through casual contact or through mosquito bites.

Regardless of the route of entry, once inside the body HIV invades certain cells of the immune system, especially those that express CD4

on their surface. CD4 acts as a cellular receptor that enables the GP-120 and GP-41 proteins on the HIV particle to fuse with the cell membrane and to release its genetic material and the enzymes needed to make new viral particles into the cytoplasm. Chief among these CD4 positive cells are the helper T lymphocytes, which are central to immune functioning. At the onset of infection, rapid viral replication and the massive killing of CD4 T cells are manifested by high levels of HIV in the blood and by a dramatic drop in T cell levels. A flu-like syndrome characterized by fever, muscle aches, headaches, enlarged lymph nodes and a rash often accompanies this acute phase. The symptoms resolve as the body produces antibody molecules that bind to and inactivate free extracellular HIV particles that are then removed by phagocytic cells. The immune system rarely is capable of removing all virus particles, many of which have entered other types of CD4 positive cells in the body. Once inside the cell, the viral reverse transcriptase is used to produce double-stranded DNA copies of the virus (provirus) that, once integrated into the cellular genome by viral integrase enzymes, may remain dormant for long periods of time. Viral replication continues at a lower but relatively steady rate which varies greatly from patient to patient and which dictates the subsequent rate of disease progression. During this chronic phase of infection, the patient shows few if any symptoms and CD4 T cell levels remain high enough to protect against other pathogenic organisms. Unfortunately, when T cells that harbor integrated proviral DNA become activated by mounting protective immune responses to HIV or other microorganisms, replication of the cell results in the production of new copies of proviral DNA as well as the viral proteins and enzymes needed to produce new HIV viral particles. These new viral particles bud from the cell membrane to infect other CD4 positive cells. If enough particles are released the cell that produced them may be killed. Large numbers of uninfected CD4 positive cells are also killed by formation of syncytia, large aggregates of cells stuck together and rendered infective by the GP-120 on the viral surface.

Over time, the CD4 T cell levels gradually decline from a normal level of approximately 800 cells per cubic millimeter. As the levels dip below 200, HIV levels in the blood increase and microorganisms that the immune system would normally control begin to proliferate, giving rise to the potentially deadly opportunistic infections such as *Pneumocystis carinii pneumonia, Cryptosporidium parvum diarrhea* and *Toxoplasma gondhii encephalitis* that are the hallmarks of AIDS. Other manifestations of the severe immunodeficiency caused by HIV include malignancies such as Kaposi's sarcoma. Despite aggressive treatment, these malignancies and opportunistic infections in the absence of a functioning immune system are usually the proximal causes of death in AIDS patients.

In general, HIV infection progresses more rapidly in children, who have almost always contracted the virus from their mother (approximately 26% of infants born to untreated mothers infected with HIV acquire HIV infection). The infection retards growth, impairs intellectual development and motor coordination and leads to the immune dysfunction of AIDS and death more rapidly than in adults. Persistently high viral loads, characteristic of HIV infections in infants and young children, are associated with faster disease progression and short survival, even with treatment. Children tend to contract more bacterial infections than adults do and 20% of pediatric AIDS patients battle serious, recurring infections such as pneumonia and meningitis. Others suffer from repeated bouts with childhood viral infections such as chicken pox. Approximately 20% of cases of vertical transmission can be prevented by the treatment of pregnant HIV-infected women with zidovudine (AZT) during pregnancy and delivery followed by short-term AZT treatment of newborns.

The HIV testing algorithm recommended by the U.S. Public Health Service comprises initial screening using an FDA-licensed enzyme immunoassay (EIA) followed by confirmatory testing of repeatedly positive EIA's with a supplemental test such as the Western blot or immunofluorescence assay. Although each of these tests for HIV-specific antibody is highly sensitive and specific, the use of both a screening and confirmatory test greatly increases the accuracy of the results. Once a diagnosis of HIV infection has been confirmed, viral load tests that measure viral RNA per milliliter of blood plasma can be used to monitor the rate of disease progression as well as the effectiveness of treatment.

Aggressive treatment with anti-retroviral drugs can prolong life and preserve the lifestyle for HIV-positive patients by lowering viral loads, especially if treatment is initiated early, ideally in the acute stage of infection. Indeed, improvement of health and quality of life is frequently dramatic. Given that viral levels in the blood correlate closely with years of survival, successful treatment should render viral levels undetectable by six months of treatment. Anti-retroviral drugs work by blocking viral replication within cells through the inhibition of either reverse transcriptase needed for the formation of proviral DNA or the viral proteases which cleavage newly made HIV proteins in the process of making new viral particles. At present there are two classes of reverse transcriptase inhibitors, the nucleoside analogues which resemble the natural building blocks of DNA, and the nonnucleoside reverse transcriptase inhibitors. The former group includes the first anti-HIV drug, zidovudine (AZT), which was introduced in 1987. See Fig. 1.

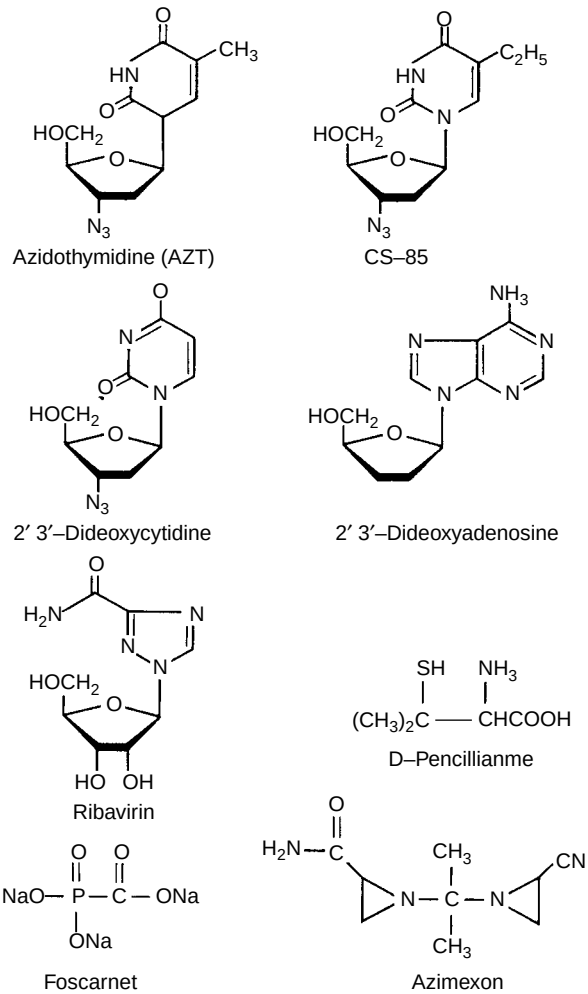

Fig. 1. Structures of some of the early anti-AIDS drugs.

To achieve maximum viral suppression and to prevent the development of viral resistance to the drugs, treatment usually consists of triple therapy, including two nucleoside analogues and a protease inhibitor: this is an expensive and prolonged course of treatment that is not without serious side effects ranging from nausea and diarrhea to neuropathy, hepatitis and diabetes. In clinical trials multi-drug regimens have been shown to reduce viral loads to undetectable levels in 75 to 85% of patients who had not been treated previously (and so were less likely to harbor resistant virus). This has resulted in a 50 to 80% decrease in hospitalizations for HIV-related problems and a similar drop in the incidence of major AIDS-related opportunistic infections. Unfortunately, failure to adhere strictly to a medication schedule and incomplete therapy can result in incomplete suppression of viral replication and the emergence of resistance mediated by mutations in viral genes. Evidence suggests that these mutations occur frequently in HIV and the non-nucleoside reverse transcriptase inhibitors, for example, can be rendered ineffective by a single mutation if it occurs in a sensitive location in the genome. Further use of an anti-HIV agent to which the virus has become resistant will "select for" the proliferation of the resistant strain unless other effective agents are used which can block all viral proliferation.

A major challenge for anti-HIV therapy is that of finding ways to eliminate the HIV provirus from resting CD4 positive T cells and other CD4 positive cells such as brain neurons and macrophages that do not actively produce viral particles but which serve as a viral reservoir. Current anti-retroviral drugs cannot eliminate these integrated viruses hidden in the cellular genome. However, experimental protocols using natural immune activators such as interleukin 2 (IL-2) to activate quiescent infected cells, forcing them to produce the virus which would then be exposed to the potent anti-HIV drugs, appears to be successful in limited trials. It is still not clear whether even apparently successful therapy can fully reconstitute an effective immune system. Even with successful viral suppression, therapy appears to only partially restore immune function, raising CD4 T cell levels by an average of 100-200 cells per cubic millimeter and the expanding system may be less effective at combating infectious agents.

Designing a vaccine to protect against infection with HIV is still as much of a challenge today as when the virus was first discovered. This is true, in part, because the natural immune antibody response to acute infection with HIV does not eliminate the virus as happens with other viral diseases such as poliomyelitis and measles for which effective vaccines are available. Further, the very immune system that a vaccine would boost is systematically attacked and destroyed by the virus. Vaccines work because they elicit a primary immune response that generates memory cells that can respond rapidly and vigorously upon subsequent exposure to the same organism. This protective secondary response requires the presence of the memory cells working in concert with functional CD4 T lymphocytes that are destroyed by HIV. The mutability of the virus has also presented significant difficulties in the quest for a vaccine. Antibodies produced in response to the surface antigens of a vaccine strain can only protect against strains of HIV that are the same or very similar to those used to generate the vaccine. This means that any changes in the surface antigens of the virus would render the vaccine worthless.

More recent vaccine development strategies include the selective stimulation of cell-mediated rather than antibody mediated immunity through the manufacture of live vector vaccines (non-HIV viruses which are genetically engineered to carry genes encoding HIV proteins) and naked DNA vaccines containing one or more HIV genes. These vaccines would generate activated cytotoxic T lymphocytes capable of recognizing and killing all cells displaying viral peptides including HIV-infected cells. In reality, the most effective strategies will probably incorporate elements that will stimulate both antibody and cell-mediated immune responses. Engineering a live attenuated vaccine that can elicit strong immune responses of both types without giving rise to AIDS might do this most effectively. This is the object of researchers who, by systematically deleting genes critical for HIV replication, hope to create a variant of the virus safe enough to ensure the impossibility of reversion to the disease-causing wild type. It remains to be seen whether or not a fully protective vaccine against HIV is possible. However, even a partially effective vaccine could be valuable in limiting the viral load in HIV-positive individuals, thus potentially reducing their symptomatology as well as their infectiveness for others. In any event, much work remains to be done before a safe and effective vaccine against HIV is available.

With a vaccine still years away, prevention of infection with HIV through behavioral change, especially behaviors associated with sex and drug use, remains the primary way to control the AIDS epidemic in which 16,000 people become infected worldwide every day. Public health has focused upon encouraging the adoption of safer sexual practices, notably condom use. Although controversial, studies have shown that the provision of condoms to young people in high schools effectively prevents infection without a feared increase in the number of sex partners. Comprehensive sex education in schools promotes safer sex while decreasing sexual activity among young people, especially among adolescents who receive the education before they are sexually active. AIDS prevention education is most effective when it is targeted to specific at-risk populations. The experience of San Francisco's gay community in the 1980's where new infections with HIV declined from approximately 8000 in 1982 to less than 400 per year today following education about the risks of unprotected anal intercourse is a case in point. Testing for HIV with follow-up counseling helps to reduce risky behaviors between HIV-positive individuals and their uninfected partners. And direct educational outreach to drug users with provision of access to clean needles can help to protect those using IV drugs without leading to greater drug abuse. In regions where needles have been made readily available, needle sharing has dropped from over 50 to less than 30% and street purchases of syringes have dropped from 75 to less than 30%. While these strategies are proving to be effective in industrialized societies, much still remains to be done in developing countries where the AIDS pandemic is still out of control. It remains to be seen how culturally sensitive educational and prevention measures will be implemented in the more populous and poorer regions of the global community.

Just a few short years ago an HIV positive diagnosis was virtually a death sentence, as the victim's prognosis was that of an almost invariably progressive debilitating and lethal disease. Although scientific understanding remains far from perfect and no "cure for AIDS" is in sight, therapeutic advances achieved in just a few short years have changed the physician's task in many cases from easing symptoms and preparing patients to die, to preserving quality of life and helping them to live. Thus, the continuing AIDS story has few parallels in the history of medicine. See also **Human Immunodeficiency Viruses (HIV)**; and **Immune System and Immunology**.

ACROMEGALY. A disease associated with the pituitary gland. The condition has been known since antiquity, but was not specifically described as a distinct clinical syndrome until 1886 by P. Marie, a French physician and medical researcher. The pituitary source of acromegaly

was confirmed by Cushing in 1909. Dr. Cushing proposed that the cause is an excessive secretion of growth-promoting hormone by a hyperfunctioning pituitary gland. Within the last decade or two, much progress has been made toward a better understanding of acromegaly. This is well documented by Melmed (1990). When the underlying conditions develop early in life, the result may be *giantism*, where individuals may attain a height of 8 feet (2.4 meters) or more. If the condition develops later in life, after bones have ceased to grow, an overactive pituitary causes excessive stimulation of growth centers, resulting in the condition known as *acromegaly*. This condition is frequently characterized by an abnormal development of feet and hands, an abnormally prominent jaw, and enlarged bones of the skull, sometimes causing the appearance like that of a primitive human.

Acromegaly occurs just as frequently in both men and women; the annual incidence is estimated at 3 to 4 cases per million and thus is rare. Mean age at diagnosis is about 40 years in men and 45 years in women. It is important to point out, however, that, because of so many unreported or undiagnosed cases, the occurrence worldwide is from 50 to 70 cases per million of population. Major life-threatening diseases associated with acromegaly include hypertension, diabetes, pulmonary infections, and cancer. Because the mortality associated with acromegaly is approximately double that of healthy subjects at the same age, once diagnosed it should be treated aggressively. The underlying cause is a pituitary adenoma, which normally shows up by using magnetic resonance imaging or computerized tomography. Once identified, therapy includes surgical treatment, radiation treatment, and drug therapy, including bromocriptine, a lysergicacid–ergot derivative and a dopamine agonist. A recently developed long-acting somatostatin analogue octreotide also appears promising.

See also **Pituitary Gland**.

ACRYLIC ACID AND DERIVATIVES. Acrylic acid, [CAS: 79-10-7], (propenoic acid) was first prepared in 1847 by air oxidation of acrolein. Interestingly, after use of several other routes over the past half century, it is this route, using acrolein from the catalytic oxidation of propylene, that is currently the most favored industrial process. Polymerization of acrylic esters has been known for just over a century. However, it was not until 1930 that the technical difficulties of their manufacture and polymerization were overcome.

Acrylates are primarily used to prepare emulsion and solution polymers. The emulsion polymerization process provides high yields of polymers in a form suitable for a variety of applications. Acrylate emulsions are used in the preparation of both interior and exterior paints, floor polishes, and adhesives. See also **Adhesives**. Solution polymers of acrylates, frequently with minor concentrations of other monomers, are employed in the preparation of industrial coatings. Polymers of acrylic acid can be used as superabsorbents in disposable diapers, as well as in formulation of superior, reduced-phosphate-level detergents.

The polymeric products can be made to vary widely in physical properties through controlled variation in the ratios of monomers employed in their preparation, cross-linking, and control of molecular weight. They share common qualities of high resistance to chemical and environmental attack, excellent clarity, and attractive strength properties. See also **Acrylic Ester Polymers**. In addition to acrylic acid itself, methyl, ethyl, butyl, isobutyl, and 2-ethylhexyl acrylates are manufactured on a large scale and are available in better than 98–99% purity. They usually contain 10–200 ppm of hydroquinone monomethyl ether as polymerization inhibitor.

Physical properties of acrylic acid and representative derivatives appear in Table 1.

Acrylic acid and its esters may be viewed as derivatives of ethylene, in which one of the hydrogen atoms has been replaced by a carboxyl or carboalkoxyl group. This functional group may display electron-withdrawing ability through inductive effects of the electron-deficient carbonyl carbon atom, and electron-releasing effects by resonance involving the electrons of the carbon–oxygen double bond. Therefore, these compounds react readily with electrophilic, free-radical, and nucleophilic agents.

Higher alkyl acrylates and alkyl-functional esters are important in copolymer products, in conventional emulsion applications for coatings and adhesives, and as reactants in radiation-cured coatings and inks. In general, they are produced in direct or transesterification batch processes because of their relatively low volume.

Direct, acid catalyzed esterification of acrylic acid is the main route for the manufacture of higher alkyl esters. The most important higher alkyl acrylate is 2-ethylhexyl acrylate prepared from the available oxo alcohol 2-ethyl-1-hexanol. The most common catalysts are sulfuric or toluenesulfonic acid and sulfonic acid functional cation-exchange resins. Solvents are used as entraining agents for the removal of water of reaction. The product is washed with base to remove unreacted acrylic acid and catalyst and then purified by distillation. The esters are obtained in 80–90% yield and in excellent purity.

The relatively low flash points of some acrylates create a fire hazard. Also, the ease of polymerization must be borne in mind in all operations. The lower and upper explosive limits for methyl acrylate are 2.8 and 25 vol %, respectively. Corresponding limits for ethyl acrylate are 1.8 vol % and saturation, respectively. All possible sources of ignition of monomers must be eliminated.

The toxicity of common acrylic monomers has been characterized in animal studies using a variety of exposure routes. Toxicity varies with level, frequency, duration, and route of exposure. The simple higher esters of acrylic acid are usually less absorbed and less toxic than lower esters. In general, acrylates are more toxic than methacrylates.

Current TLV/TWA values are provided in Material Safety Data Sheets provided by manufacturers on request.

ACRYLIC PLASTICS. A wide range of plastic materials dates back to the pioneering work of Redtenbacher before 1850 who prepared acrylic acid by oxidizing acrolein

$$CH{=}CHCHO \xrightarrow{O} CH_2{=}CHCOOH$$

At a considerably later date, Frankland prepared ethyl methacrylate and methacrylic acid from ethyl α-hydroxyisobutyrate and phosphorus trichloride. Tollen prepared acrylate esters from 2,3-dibromopropionate esters and zinc. Otto Rohm, in 1901, described the structures of the liquid condensation products (including dimers and trimers) obtained from the action of sodium alkoxides on methyl and ethyl acrylate. Shortly after World War I, Rohm introduced a new acrylate synthesis, noting that an acrylate is formed in good yield from heating ethylene cyanohydrin and sulfuric acid and alcohol. A major incentive for the development of a clear, tough plastic acrylate was for use in the manufacture of safety glass.

Ethyl methacrylate went into commercial production in 1933. The synthesis proceeded in the following steps:

(1) Acetone and hydrogen cyanide, generated from sodium cyanide and acid, gave acetone cyanohydrin

$$HCN + CH_3COCH_3 \longrightarrow (CH_3)_2C(OH)CN$$

(2) The acetone cyanohydrin was converted to ethyl α-hydroxyisobutyrate by reaction with ethyl alcohol and dilute sulfuric acid

$$(CH_3)_2C(OH)CN + C_2H_5OH \xrightarrow{H_2SO_4} (CH_3)_2C(OH)COOC_2H_5$$

(3) The hydroxy ester was dehydrated with phosphorus pentoxide to produce ethyl methacrylate

$$(CH_3)_2C(OH)COOC_2H_5 \xrightarrow{P_2O_5} CH_2{=}C(CH_3)COOC_2H_5$$

In 1936, the methyl ester of methacrylic acid was introduced and used to produce an "organic glass" by cast polymerization. Methyl methacrylate was made initially through methyl α-hydroxyisobutyrate by the same process previously indicated for the ethyl ester. Over the years, numerous process changes have taken place and costs lowered, making these plastics available on a very high tonnage basis for thousands of uses. For example, the hydrogen cyanide required is now produced catalytically from natural gas, ammonia, and air.

As with most synthetic plastic materials, they commence with the monomers. Any of the common processes, including bulk, solution, emulsion, or suspension systems, may be used in the free-radical polymerization or copolymerization of acrylic monomers. The molecular weight and physical properties of the products may be varied over a wide range by proper selection of acrylic monomer and monomer mixes, type of process, and process conditions.

In bulk polymerization no solvents are employed and the monomer acts as the solvent and continuous phase in which the process is carried out. Commercial bulk processes for acrylic polymers are used mainly in the production of sheets, rods and tubes. Bulk processes are also used on a much smaller scale in the preparation of dentures and novelty items and in the preservation of biological specimens. Acrylic castings are produced by pouring monomers or partially polymerized syrups into suitably designed molds and completing the polymerization. Acrylic bulk polymers consist essentially of poly(methyl methacrylate) or copolymers with methyl methacrylate as the major component. Free radical initiators soluble in the monomer, such as benzoyl peroxide, are the catalysts for the polymerization. Aromatic tertiary amines, such as dimethylaniline, may be used as accelerators in conjunction with the peroxide to permit curing at room temperature. However, colorless products cannot be obtained with amine accelerators because of the formation of red or yellow colors. As the polymerization proceeds, a considerable reduction in volume occurs which must be taken into consideration in the design of molds. At 25 °C, the shrinkage of methyl methacrylate in the formation of the homopolymer is 21%.

Solutions of acrylic polymers and copolymers find wide use as thermoplastic coatings and impregnating fluids, adhesives, laminating materials, and cements. Solutions of interpolymers convertible to thermosetting compositions can also be prepared by inclusion of monomers bearing reactive functional groups which are capable of further reaction with appropriate cross-linking agents to give three-dimensional polymer networks. These polymer systems may be used in automotive coatings and appliance enamels, and as binders for paper, textiles, and glass or non-woven fabrics. Despite the relatively low molecular weight of the polymers obtained in solution, such products are often the most appropriate for the foregoing uses. Solution polymerization of acrylic esters is usually carried out in large stainless steel, nickel, or glass-lined cylindrical kettles, designed to withstand at least 50 psig. The usual reaction mixture is a 40–60% solution of the monomers in solvent. Acrylic polymers are soluble in aromatic hydrocarbons and chlorohydrocarbons.

Acrylic emulsion polymers and copolymers have found wide acceptance in many fields, including sizes, finishes and binders for textiles, coatings and impregnants for paper and leather, thermoplastic and thermosetting protective coatings, floor finishing materials, adhesives, high-impact plastics, elastomers for gaskets, and impregnants for asphalt and concrete.

Advantages of emulsion polymerization are rapidity and production of high-molecular-weight polymers in a system of relatively low viscosity. Difficulties in agitation, heat transfer, and transfer of materials are minimized. The handling of hazardous solvents is eliminated. The two principal variations in technique used for emulsion polymerization are the redox and the reflux methods.

Suspension polymerization also is used. When acrylic monomers or their mixtures with other monomers are polymerized while suspended (usually in aqueous system), the polymeric product is obtained in the form of small beads, sometimes called pearls or granules. Bead polymers are the basis of the production of molding powders and denture materials. Polymers derived from acrylic or methacrylic acid furnish exchange resins of the carboxylic acid type. Solutions in organic solvents furnish lacquers, coatings and cements, while water-soluble hydrolysates are used as thickeners, adhesives, and sizes.

The basic difference between suspension and emulsion processes lies in the site of the polymerization, since initiators insoluble in water are used in the suspension process. Suspensions are produced by vigorous and continuous agitation of the monomer and solvent phases. The size of the drop will be determined by the rate of agitation, the interfacial tension, and the presence of impurities and minor constituents of the recipe. If agitation is stopped, the droplets coalesce into a monomer layer. The water serves as a dispersion medium and heat-transfer agent to remove the heat of polymerization. The process and resulting product can be influenced by the addition of colloidal suspending agents, thickeners, and salts.

Product Groupings. The principal acrylic plastics are cast sheet, molding powder, and high-impact molding powder. The cast acrylic sheet is formable, transparent, stable, and strong. Representative uses include architectural panels, aircraft glazing, skylights, lighted outdoor signs, models, product prototypes, and novelties. Molding powders are used in the mass production of numerous intricate shapes, such as automotive lights, lighting fixture lenses, and instrument dials and control panels for autos, aircraft, and appliances. The high-impact acrylic molding powder yields a somewhat less transparent product, but possesses unusual toughness for such applications as toys, business machine components, blow-molded bottles, and outboard motor shrouds. The various acrylic resins find numerous uses as previously mentioned, with varied and wide use in coatings. Acrylic latexes are composed mainly of monomers of the acrylic family, such as methyl methacrylate, butyl methacrylate, methyl acrylate, and 2-ethyl hexylacrylate. Additional monomers, such as styrene or acrylonitrile, can be polymerized with acrylic monomers. Acrylic latexes vary considerably in their properties, mainly affected by the monomers used, the particle size, and the surfactant system of the latex. Generally, acrylic latexes are cured by loss of water only, do not yellow, possess good exterior durability, are tough, and usually have good abrasion resistance. The acrylic polymers are reasonably costly and some latexes do not have very good color compatibility. Acrylic latex paints can be used for concrete floors, interior flat and semigloss finishes, and exterior surfaces. See also **Paints and Coatings**.

A developing and potentially large volume use for acrylics is in the video, audio, and data-storage disk markets. The properties, as well as ease of fabrication, have made acrylics a primary choice for these applications.

ACRYLONITRILE. Acrylonitrile, [CAS: 107-13-1], is among the top 50 chemicals produced in the United States as a result of the tremendous growth in its use as a starting material for a wide range of chemical and polymer products. Acrylic fibers remain the largest use of acrylonitrile; other significant uses are in resins and nitrile elastomers and as an intermediate in the production of adiponitrile and acrylamide.

Acrylonitrile (C_3H_3N mol wt = 53.064) is an unsaturated molecule having a carbon–carbon double bond conjugated with a nitrile group. It is a polar molecule because of the presence of the nitrogen heteroatom. Table 1 lists some properties for acrylonitrile.

TABLE 1. PHYSICAL PROPERTIES OF ACRYLONITRILE

Property	Value
Appearance/odor	Clear, colorless liquid with faintly pungent odor
Boiling point, °C	77.3
Freezing point, °C	−83.5
Density, 20 °C, g/cm^3	0.806
Vapor density (air = 1)	1.8
pH (5% aqueous solution)	6.0–7.5
Viscosity, 25 °C, mPa·s(=cP)	0.34
Flash point, °C	0
Autoignition temperature, °C	481
Heat of combustion, liquid, 25 °C, kJ/mol	1761.5
Heat of vaporization, 25 °C, kJ/mol	32.65

To convert kJ to kcal, divide by 4.184.

Acrylonitrile is miscible in a wide range of organic solvents, including acetone, benzene, carbon tetrachloride, diethyl ether, ethyl acetate, ethylene cyanohydrin, petroleum ether, toluene, some kerosenes, and methanol.

Acrylonitrile has been characterized using infrared, Raman, and ultraviolet spectroscopies, electron diffraction, and mass spectroscopy.

Acrylonitrile undergoes a wide range of reactions at its two chemically active sites, the nitrile group and the carbon–carbon double bond. Detailed descriptions of specific reactions have been given. Acrylonitrile polymerizes readily in the absence of a hydroquinone inhibitor, especially when exposed to light. Polymerization is initiated by free radicals, redox catalysts, or bases and can be carried out in the liquid, solid, or gas phase. Homopolymers and copolymers are most easily produced using liquid-phase polymerization. See also **Acrylonitrile Polymers**.

Acrylonitrile is produced in commercial quantities almost exclusively by the vapor-phase catalytic propylene ammoxidation process developed by Sohio.

$$C_3H_6 + NH_3 + \frac{3}{2}O_2 \xrightarrow{\text{catalyst}} C_3H_3N + 3\ H_2O$$

Acrylonitrile must be stored in tightly closed containers in cool, dry, well-ventilated areas away from heat, sources of ignition, and incompatible chemicals. Storage vessels, such as steel drums, must be protected against physical damage, with outside detached storage preferred. Storage tanks and equipment used for transferring acrylonitrile should be electrically grounded to reduce the possibility of static spark-initiated fire or explosion. Acrylonitrile is regulated in the workplace by OSHA (29 CFR 1910).

Acrylonitrile is transported by rail car, barge, and pipeline. Department of Transportation (DOT) regulations require labeling acrylonitrile as a flammable liquid and poison.

Acrylonitrile is highly toxic if ingested, and it is extremely irritating and corrosive to skin and eyes. Acrylonitrile is categorized as a cancer hazard by OSHA.

Acrylonitrile will polymerize violently in the absence of oxygen if initiated by heat, light, pressure, peroxide, or strong acids and bases. It is combustible and ignites readily, producing toxic combustion products such as hydrogen cyanide, nitrogen oxides, and carbon monoxide.

Federal regulations (40 CFR 261) classify acrylonitrile as a hazardous waste, and it is listed as Hazardous Waste Number U009. Disposal must be in accordance with federal (40 CFR 262, 263, 264), state, and local regulations only at properly permitted facilities.

ACTH. [CAS: 9002-60-2] The adrenocorticotropic hormone of the anterior lobe of the pituitary gland, which specifically stimulates the adrenal cortex to secrete cortisone, and hence has effects identical with those of cortisone. ACTH differs in its chemistry, absorption, and metabolism from the other adrenal steroids. Chemically, it is a water-soluble polypeptide having a molecular weight of about 3500. Its complete amino acid sequence has been determined. It produces its peripheral physiological effects by causing discharge of the adrenocortical steroids into the circulation. ACTH has been extracted from pituitary glands. In purified form, ACTH is useful in treating some forms of arthritis, lupus erythematosus, and severe skin disorders. The action of ACTH injections parallels the result of large quantities of naturally formed cortisone if they were released naturally. See also **Adrenal Disease; Adrenal Glands; Hormones; Central and Peripheral Nervous Systems and the Brain; Pituitary Gland**; and **Steroids**.

ACTIN. One of the two proteins that makes up the myofibrils of striated muscles. The other protein is myosin. The combination of these two proteins is sometimes spoken of as actinomyosin. The banded nature of the myofibrils is due to the fact that both proteins are present where the bands are dark and only one or the other is present in the light bands. Since these bands lie side by side in the different myofibrils that go to make up a muscle fiber, the entire muscle fiber shows a banded or striated appearance. See also **Contractility and Contractile Proteins**.

ACTINIDE CONTRACTION. An effect analogous to the Lanthanide contraction, which has been found in certain elements of the Actinide series. Those elements from thorium (atomic number 90) to curium (atomic number 96) exhibit a decreasing molecular volume in certain compounds, such as those which the actinide tetrafluorides form with alkali metal fluorides, plotted in Fig. 1. The effect here is due to the decreasing crystal radius of the tetrapositive actinide ions as the atomic number increases. Note that in the Actinides the tetravalent ions are compared instead of the trivalent ones as in the case of the Lanthanides, in which the trivalent state is by far the most common.

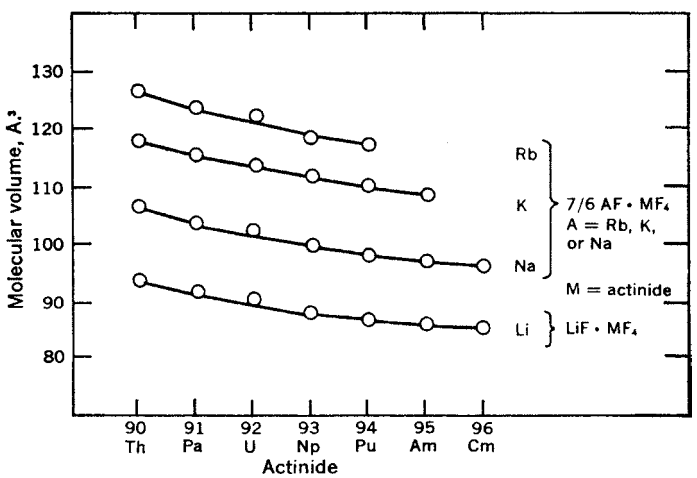

Fig. 1. Plot of molecular volume versus atomic number of the tetravalent Actinides.

The behavior is attributed to the entrance of added electrons into an (inner) f shell ($4f$ for the Lanthanides, $5f$ for the Actinides) so that the increment they produce in atomic volume is less than the reduction due to the greater nuclear charge.

ACTINIDES AND TRANSACTINIDES

Actinides

The actinide elements are a group of chemically similar elements with atomic numbers 89 through 103, and their names, symbols, and atomic numbers are given in Table 1, see also **Radioactivity**; **Nuclear Power Technology**; **Plutonium**; **Thorium**; and **Uranium**.

Each of the elements has a number of isotopes, all radioactive and some of which can be obtained in isotopically pure form. More than 200 in number and mostly synthetic in origin, they are produced by neutron or charged-particle-induced transmutations. The known radioactive isotopes are distributed among the 15 elements approximately as follows: actinium, 29; thorium, 28; protactinium, 27; uranium, 22; neptunium, 20; plutonium, 18; americium, 14; curium, 15; californium, 20; einsteinium, 16; fermium, 18; berkelium, 12; mendelevium, 16 nobelium, 12; and lawrencium, 10. There is frequently a need for values to be assigned for the atomic weights of the actinide elements. Any precise experimental work would require a value for the isotope or isotopic mixture being used, but where there is a purely formal demand for atomic weights, mass numbers that are chosen on the basis of half-life and availability have customarily been used. A list of these is provided in Table 1.

Thorium and uranium have long been known, and uses dependent on their physical or chemical, not on their nuclear, properties were developed prior to the discovery of nuclear fission. The discoveries of actinium and protactinium were among the results of the early studies of naturally radioactive substances. The first transuranium element, synthetic neptunium, was discovered during an investigation of nuclear fission, and this event rapidly led to the discovery of the next succeeding element, plutonium. The realization that plutonium as ^{239}Pu undergoes fission with slow neutrons and thus could be utilized in a nuclear weapon supplied the impetus for its thorough investigation. This research has provided the background of knowledge and techniques for the production and identification of nine more actinide elements and three transactinide elements by 1974.

After a lapse of nearly seven years, a new production reaction and a new on-line separation technique were used to identify six more actinide elements (107–112) between 1981 and 1996. See also **Chemical Elements**. In 1999, evidence was reported for production and detection of the SuperHeavy Elements (SHEs) 114, 116, and 118. These elements are near the "island of nuclear stability" calculated in the mid-1960s to be at proton number 114 (or possibly 126) and neutron number 184 because of the extra stability resulting from the filling of the spherical shells predicted at those so-called "magic" numbers.

Thorium, uranium, and plutonium are well known for their role as the basic fuels (or sources of fuel) for the release of nuclear energy. The importance of the remainder of the actinide group lies at present, for the most part, in the realm of pure research, but a number of practical applications are also known. The actinides present a storage-life problem in nuclear waste disposal and consideration is being given to separation methods for their recovery prior to disposal. See also **Nuclear Power Technology**.

Source. Only the members of the actinide group through Pu have been found to occur in nature. Thorium and uranium occur widely in the earth's crust in combination with other elements, and, in the case of uranium, in significant concentrations in the oceans. With the exceptions of uranium and thorium, the actinide elements are synthetic in origin for practical purposes, i.e., they are products of nuclear reactions. High neutron fluxes are available in modern nuclear reactors, and the most feasible method for preparing actinium, protactinium, and most of the actinide elements is through the neutron irradiation of elements of high atomic number.

The close chemical resemblance among many of the actinide elements permits their chemistry to be described for the most part in a correlative way.

The oxidation states of the actinide elements are summarized in Table 2. The most stable states are designated by boldface type and those which are very unstable are indicated by parentheses.

TABLE 2. THE OXIDATION STATES OF THE ACTINIDE ELEMENTS

				7	(7)									

The actinide elements exhibit uniformity in ionic types. Corresponding ionic types are similar in chemical behavior, although the oxidation–reduction relationships and therefore the relative stabilities differ from element to element.

Of the actinide ions, the small, highly charged M^{4+} ions exhibit the greatest degree of hydrolysis and complex ion formation.

The degree of hydrolysis or complex ion formation decreases in the order $M^{4+} > MO_2^{2+} > M^{3+} > MO_2^{+}$. Presumably the relatively high tendency toward hydrolysis and complex ion formation of MO ions is related to the high concentration of charge on the metal atom. On the basis of increasing charge and decreasing ionic size, it could be expected that the degree of hydrolysis for each ionic type would increase with increasing atomic number.

The actinide metals, like the lanthanide metals, are highly electropositive. They can be prepared by the electrolysis of molten salts or by the

reduction of a halide with an electropositive metal, such as calcium or barium.

Solid Compounds. Thousands of compounds of the actinide elements have been prepared.

The binary compounds with carbon, boron, nitrogen, silicon, and sulfur are not included; these are of interest, however, because of their stability at high temperatures. A large number of ternary compounds, including numerous oxyhalides, and more complicated compounds have been synthesized and characterized. These include many intermediate (nonstoichiometric) oxides, and besides the nitrates, sulfates, peroxides, and carbonates, compounds such as phosphates, arsenates, cyanides, cyanates, thiocyanates, selenocyanates, sulfites, selenates, selenites, tellurates, tellurites, selenides, and tellurides.

Crystal structure data have provided the basis for the ionic radii (coordination number=CN=6). For both M^{3+} and M^4 ions there is an actinide contraction, analogous to the lanthanide contraction, with increasing positive charge on the nucleus. As a consequence of the ionic character of most actinide compounds and of the similarity of the ionic radii for a given oxidation state, analogous compounds are generally isostructural.

The absorption spectra of actinide and lanthanide ions in aqueous solution and in crystalline form contain narrow bands in the visible, near-ultraviolet, and near-infrared regions of the spectrum.

Transactinides and Superheavy Elements

The elements beyond the actinides in the periodic table can be termed the transactinides. These begin with the element having the atomic number 104 and extend, in principle, indefinitely. Although only seven such elements, numbers 104–110 were definitely known in 2003, (Rutherfordium 104, Dubnium 105, Seaborgium 106, Bohrium 107, Hassium 108, Meitnerium 109, and Darmstadtium 110), there are good prospects for the discovery of a number of additional elements just beyond number 110 or in the region of larger atomic numbers. They are synthesized by the bomunderlinedment of heavy nuclides with heavy ions. See also **Chemical Elements**.

On the basis of the simplest projections it is expected that the half-lives of the elements beyond element 110 will become shorter as the atomic number is increased, and this is true even for the isotopes with the longest half-life for each element.

Turning to consideration of electronic structure, upon which chemical properties must be based, modern high speed computers have made possible the calculation of such structures. The calculations show that elements 104 through 112 are formed by filling the 6*d* electron subshell, which makes them, as expected, homologous in chemical properties with the elements hafnium ($Z = 72$) through mercury ($Z = 80$). Elements 113 through 118 result from the filling of the 7*p* subshell and are expected to be similar to the elements thallium ($Z = 81$) through radon ($Z = 86$).

It can be seen that elements in and near the island of stability based on element 114 can be predicted to have chemical properties as follows: element 114 should be a homologue of lead, that is, should be eka-lead; and element 112 should be eka-mercury, element 110 should be eka-platinum, etc. If there is an island of stability at element 126, this element and its neighbors should have chemical properties like those of the actinide and lanthanide elements.

ACTINIUM. [CAS: 7440-34-8.] Actinium, chemical element symbol Ac, at. no. 89, at. wt. 227 (mass number of the most stable isotope), periodic table group 3, is classed in the periodic system as a higher homologue of lanthanum. The electronic configuration for actinium is

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 6s^2 6p^6 6d^1 7s^2$$

The ionic radius (Ac^{3+}) is 1.11 Å.

Presently, 24 isotopes of actinium, with mass numbers ranging from 207 to 230, have been identified. All are radioactive. One year after the discovery of polonium and radium by the Curies, A. Debierne found an unidentified radioactive substance in the residue after treatment of pitchblende. Debierne named the new material *actinium* after the Greek word for ray. F. Giesel, independently in 1902, also found a radioactive material in the rare-earth extracts of pitchblende. He named this material *emanium*. In 1904, Debierne and Giesel compared the results of their experimentation and established the identical behavior of the two substances. Until formulation of the law of radioactive displacement by Fajans and Soddy about ten years later, however, actinium definitely could not be classed in the periodic system as a higher homologue of lanthanum.

The isotope discovered by Debierne and also noted by Giesel was ^{227}Ac which has a half-life of 21.7 years. The isotope results from the decay of ^{235}U (AcU-*actinouranium*) and is present in natural uranium to the extent of approximately 0.715%. The proportion of Ac/U in uranium ores is estimated to be approximately 2.10^{-10} at radioactive equilibrium. O. Hahn established the existence of a second isotope of actinium in nature, ^{228}Ac, in 1908. This isotope is a product of thorium decay and logically also is referred to as *meso*-thorium, with a half-life of 6.13 hours. The proportion of mesothorium to thorium ($MsTh_2$/Th) in thorium ores is about 5.10^{-14}. The other isotopes of actinium were found experimentally as the result of bombarding thorium targets. The half-life of 10 days of ^{225}Ac is the longest of the artificially produced isotopes. Although occurring in nature as a member of the neptunium family, ^{225}Ac is present in extremely small quantities and thus is very difficult to detect.

^{227}Ac can be extracted from uranium ores where present to the extent of 0.2 mg/ton of uranium and it is the only isotope that is obtainable on a macroscopic scale and that is reasonably stable. Because of the difficulties of separating ^{227}Ac from uranium ores, in which it accompanies the rare earths and with which it is very similar chemically, fractional crystallization or precipitation of relevant compounds no longer is practiced. Easier separations of actinium from lanthanum may be effected through the use of ion-exchange methods. A cationic resin and elution, mainly with a solution of ammonium citrate or ammonium-a-hydroxyisobutyrate, are used. To avoid the problems attendant with the treatment of ores, ^{227}Ac now is generally obtained on a gram-scale by the transmutation of radium by neutron irradiation in the core of a nuclear reactor. Formation of actinium occurs by the following process:

$$^{226}Ra(n, \gamma)^{227}Ra \xrightarrow{\beta-} {}^{227}Ac$$

In connection with this method, the cross-section for the capture of thermal neutrons by radium is 23 barns (23×10^{-24} cm^2). Thus, prolonged radiation must be avoided because the accumulation of actinium is limited by the reaction ($\sigma = 500$ barns):

$$^{227}Ac(n, \gamma)^{228}Ac(MsTh_2) \longrightarrow {}^{228}Th(RdTh)$$

In 1947, F. Hageman produced 1 mg actinium by this process and, for the first time, isolated a pure compound of the element. It has been found that when 25 g of $RaCO_3$ (radium carbonate) are irradiated at a flux of 2.6×10^{14} $ncm^{-2}s^{-1}$ for a period of 13 days, approximately 108 mg of ^{227}Ac (8 Ci) and 13 mg of ^{228}Th (11 Ci) will be yielded. In an intensive research program by the Centre d'Etude de l'Energie Nucléaire Belge, Union Minière, carried out in 1970–1971, more than 10 g of actinium were produced. The process is difficult for at least two reasons: (1) the irradiated products are highly radioactive, and (2) radon gas, resulting from the disintegration of radium, is evolved. The methods followed in Belgium for the separation of ^{226}Ra, ^{227}Ac, and ^{228}Th involved the precipitation of $Ra(NO_3)_2$ (radium nitrate) from concentrated HNO_3 after which followed the elimination of thorium by adsorption on a mineral ion exchanger (zirconium phosphate) which withstand high levels of radiation without decomposition.

Metallic actinium cannot be obtained by electrolytic means because it is too electropositive. It has been prepared on a milligram-scale through

the reduction of actinium fluoride in a vacuum with lithium vapor at about 350 °C. The metal is silvery white, faintly emits a blue-tinted light which is visible in darkness because of its radioactivity. The metal takes the form of a face-centered cubic lattice and has a melting point of 1050 ± 50 °C. By extrapolation, it is estimated that the metal boils at about 3300 °C. An amalgam of metallic actinium may be prepared by electrolysis on a mercury cathode, or by the action of a lithium amalgam on an actinium citrate solution (pH = 1.7 to 6.8).

In chemical behavior, actinium acts even more basic than lanthanum (the most basic element of the lanthanide series). The mineral salts of actinium are extracted with difficulty from their aqueous solutions by means of an organic solvent. Thus, they generally are extracted as chelates with trifluoroacetone or diethylhexylphosphoric acid. The water-insoluble salts of actinium follow those of lanthanum, namely, the carbonate, fluoride, fluosilicate, oxalate, phosphate, double sulfate of potassium. With exception of the black sulfide, all actinium compounds are white and form colorless solutions. The crystalline compounds are isomorphic.

In addition to its close resemblance to lanthanum, actinium also is analogous to curium (Z = 96) and lawrencium (Z = 103), both of the group of trivalent transuranium elements. This analogy led G.T. Seaborg to postulate the actinide theory, wherein actinium begins a new series of rare earths which are characterized by the filling of the 5f inner electron shell, just as the filling of the 4f electron shell characterizes the Lanthanide series of elements. However, the first elements of the Actinide series differ markedly from those of actinium. Notably, there is a multiplicity of valences for which there is no equivalent among the lanthanides. See **Chemical Elements** for other properties of actinium.

Mainly, actinium has been of interest from a scientific standpoint. However, ^{227}Ac has been proposed as a source of heat in space vehicles. It is interesting to note that the heat produced from the absorption of the radiation emitted by 1 g of actinium, when in equilibrium with its daughters, is 12,500 cal/hour.

ACTINOLITE. The term for a calcium-iron-magnesium amphibole, the formula being $Ca_2(Mg,Fe)_5Si_8O_{22}(OH)_2$ but the amount of iron varies considerably. It occurs as bladed crystals or in fibrous or granular masses. Its hardness is 5–6, sp gr 3–3.2, color green to grayish green, transparent to opaque, luster vitreous to silky or waxy. Iron in the ferrous state is believed to be the cause of its green color. Actinolite derives its name from the frequent radiated groups of crystals. Essentially it is an iron-rich tremolite; the division between the two minerals is quite arbitrary, with color the macroscopic definitive factor — white for tremolite, green for actinolite. Actinolite is found in schists, often with serpentine, and in igneous rocks, probably as the result of the alteration of pyroxene. The schists of the Swiss Alps carry actinolite. It is also found in Austria, Saxony, Norway, Japan, and Canada in the provinces of Quebec and Ontario. In the United States actinolite occurs in Massachusetts, Pennsylvania, Maryland, and as a zinc-manganese bearing variety in New Jersey. See also **Amphibole**; **Tremolite**; and **Uralite**.

ACTINOMETER. The general name for any instrument used to measure the intensity of radiant energy. In earlier usage, the term was often restricted to the measurement of photochemically active radiation, but is now used more generally.

In meteorological and astronomical applications, actinometers may be classified according to the type of radiation they measure: (1) The *pyrheliometer* measures the intensity of direct solar radiation. It consists of a radiation-sensing element enclosed in a casing that has a small aperture through which the direct solar rays enter, and a recorder unit. The amount of radiant energy absorbed is determined from the temperature rise of the sensing element. (2) The *pyranometer* measures the combined intensity of direct solar radiation and diffuse sky radiation, i.e., radiation reaching the earth's surface after having been scattered from the direct solar beam by molecules or suspensoids in the atmosphere. It consists of a recorder and a radiation-sensing element mounted so that it views the entire sky. (3) The *pyrgeometer* measures the effective terrestrial radiation, i.e., the difference between the total outgoing infrared radiation of the earth's surface and the descending atmospheric radiation. It consists of four manganin strips, two blackened and two polished. The blackened strips are allowed to radiate to the atmosphere, whereas the polished strips are shielded. The electrical power required to equalize the temperature of the four strips is taken as a measure of the outgoing radiation.

ACTINOMETRY. The science of measurement of radiant energy, particularly that of the sun, in its thermal, chemical, and luminous aspects. See also **Actinometer**.

ACTINOMYCOSIS. An infectious disease caused by Gram-positive bacteria with a characteristic filamentous branching shape which are known as actinomycetes. Because of their unusual shape, the actinomycetes were once thought to be fungi. However, they differ from fungi in their cell wall composition, notably in the lack of chitin, and their filaments or hyphae exceed one micrometer in diameter tending to fragment into bacillary forms of subculture. There are two genera of *Actinomycetacea: Nocardia* and *Actinomycetes*. The majority of human infections are, however, caused by one species, *A. israeli*, which is an aerobic commensal of the oropharynx, normally resident in gingivodental crevices and tonsillar crypts.

Actinomycosis is an endogenous infection and case to case transmission is only likely to occur through human bites or bare-knuckle injuries by the opponent's teeth. It is a subacute or chronic granulomatous disease that progresses to fibrosis and suppuration with formation of external sinuses. *A. bovis* causes a condition known as "lumpy jaw" in cattle, but it rarely, if ever, causes human disease although the distinctive term has been applied also to cervicofacial actinomycosis.

In the past, the majority of cases of actinomycosis occurred in men, and cervicofacial, thoracic, and abdominal forms of the disease formerly constituted 95% of cases. Currently, female pelvic actinomycosis is probably the most common form of the disease.

The types of actinomycosis are generally classified on the basis of anatomical location. *Cervicofacial* actinomycosis (lumpy jaw) is associated with dental caries and usually follows orofacial trauma, dental extraction or gingival infection, together with poor dental hygiene. *Pulmonary* actinomycosis may follow aspiration of the organism from the oropharynx or by infiltration through the esophageal wall, giving rise to cough, pleuritic symptoms, fever, and weight loss. *Gastrointestinal* actinomycosis is acquired by ingestion of the organism that penetrates the intestinal wall at a site where the mucosa has been injured by disease or traumatized.

Symptoms most frequently are encountered in the right iliac fossa where differential diagnosis from appendicitis, Crohn's disease, or tuberculosis is important. *Hepatic* actinomycosis may account for up to 15% of cases, occurring primarily or secondary to pre-existing abdominal disease. The kidney may also become involved by local extension or through bacteremic spread. *Pelvic* actinomycosis may originate from the upward spread of organisms that reach the perineum from the oropharynx and via the intestinal tract. Pelvic extension from the abdomen may also occur, but the disease mostly has been observed in women fitted with plastic intrauterine contraceptive devices, notably the Dalkon shield. The extension of infection ranges from cervicitis and endometritis to salpingitis and tubovarian abscess.

Wherever the site of the infection, however, actinomycosis characteristically produces a chronic granulomatous inflammation which burrows deeply through contiguous tissue without respect to fascial planes. Consequently, draining sinus tracts are often present. The drainage may be purulent or sanguineous. If present, sulfur granules, small white-to-yellow aggregates of bacterial filaments, are important clues to diagnosis. The disease follows an indolent but progressive course and, in the typical case, symptoms are present for one to five months before diagnosis.

The diagnosis of actinomycosis depends upon the microscopic identification of the organism after smear or culture. Although wide surgical excision is not ordinarily required for treatment, some surgical debridement may be helpful therapeutically. Otherwise, antibiotics are the mainstay of treatment, with penicillin being the drug of choice. In the penicillin-allergic

patient, tetracycline is preferred. With vigorous antibiotic treatment, the prognosis is excellent.

University of South Florida, Tampa, FL

ACTINON. The name of the isotope of radon (emanation), which occurs in the naturally occurring actinium series (see **Chemical Elements**; and **Radioactivity**), being produced by alpha-decay of actinium X, which is itself a radium isotope. Actinon has an atomic number of 86, a mass number of 219, and a half-life of 3.92 seconds, emitting an alpha particle to form polonium-215 (Actinium A).

ACTION. The action of a dynamical system is the space integral of the total momentum of the system. Specifically, if $\mathbf{r}_j$ is the position vector of the jth particle of the system, $\dot{\mathbf{r}}_j$ is its time rate of change, and m_j is the mass, the action for the path going from P_1 to P_2 is

$$\int_{P1}^{P2} \sum m_j \dot{\mathbf{r}}_j \cdot d\mathbf{r}_j$$

where the integral is taken along the actual path from P_1 to P_2. The integral can be shown to reduce to the form

$$2\int_{t1}^{t2} E_K dt$$

where E_K is the total kinetic energy of the system and t_1 and t_2 are the times at which the system is in positions P_1 and P_2 respectively. See **Least Action (Principle of)**.

ACTION CURRENT. The local flow of current into the depolarized region of the cell membrane during the generation of the action potential. Since the flow of current from adjacent regions is an outward current — namely, a depolarizing current — under normal conditions it serves to depolarize the cell membrane in such regions beyond the threshold. By repetition of this process in successive regions, a self-propagated depolarization of the membrane sweeps along the nerve fiber. The nerve impulse is thus a consequence of the local action currents.

ACTION POTENTIAL. A characteristic variation in the membrane potential (i.e., potential across cell membrane) of excitable cells when the cell is stimulated. The potential falls rapidly in time toward zero, "overshoots," making the inside positive for a brief interval of time, and finally returns to the resting state. In many nerve and muscle cells, the duration of the action potential is found to be fractions of a millisecond to several milliseconds (Fig. 1). The action potential is triggered by a depolarizing current when the membrane potential falls to the threshold level. See **Action Current**.

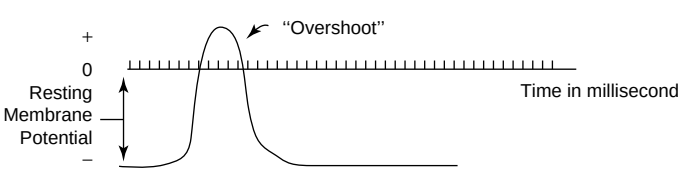

Fig. 1. Action potential.

The action polarization is of particular interest in the passage of an impulse along a nerve fiber. At rest, the interior of a nerve fiber is negative to the exterior, with a potential difference of 50 to 100 millivolts; stimulation of the nerve sets up a negative wave of 70 to 100 millivolts, lasting one millisecond, followed by a brief refractory period during which further stimulation is ineffective. The record of such a change, as shown by a sensitive galvanometer, exhibits a characteristic sharp spike. Somewhat similar changes accompany muscular contraction. The study of action potentials has much practical importance e.g., electrocardiography, electroencephalography, and electromyography. See also **Central and Peripheral Nervous Systems and The Brain.**

ACTION SPECTRUM. A graph of the amount of biological response produced by incident light as a function of wavelength. Thus, one might construct a dose-response curve for each wavelength of light used in the inactivation of an enzyme by ultraviolet light. The relative efficiency with which the inactivation is produced plotted versus wavelength of the incident light is the action spectrum for the inactivation of that enzyme.

ACTIVATED CARBON. See **Adsorption (Process)**; and **Decolorizing Agent**.

ACTIVATED SLUDGE. Activated sludge is the biologically active sediment produced by the repeated aeration and settling of sewage and/or organic wastes. The dissolved organic matter acts as food for the growth of an aerobic flora. This flora produces a biologically active sludge which is usually brown in color and which destroys the polluting organic matter in the sewage and waste. The process is known as the activated sludge process.

The activated sludge process, with minor variations, consists of aeration through submerged porous diffusers or by mechanical surface agitation, of either raw or settled sewage for a period of 2–6 hours, followed by settling of the solids for a period of 1–2 hours. These solids, which are made up of the solids in the sewage and the biological growths that develop, are returned to the sewage flowing into the aeration tanks. As this cycle is repeated, the aerobic organisms in the sludge develop until there is 1000–3000 ppm of suspended sludge in the aeration liquor. After a while, more of the active sludge is developed than is needed to purify the incoming sewage, and this excess is withdrawn from the process and either dried for fertilizer or digested anaerobically with raw sewage sludge. This anaerobic digestion produces a gas consisting of approximately 65% methane and 35% CO_2, and changes the water-binding properties so that the sludge is easier to filter or dry.

The activated sludge is made up of a mixture of zoogleal bacteria, filamentous bacteria, protozoa, rotifera, and miscellaneous higher forms of life. The types and numbers of the various organisms will vary with the types of food present and with the length of the aeration period. The settled sludge withdrawn from the process contains from 0.6 to 1.5% dry solids, although by further settling it may be concentrated to 3–6% solids. Analysis of the dried sludge for the usual fertilizer constituents show that it contains 5–6% of slowly available N and 2–3% of P. The fertilizing value appears to be greater than the analysis would indicate, thus suggesting that it contains beneficial trace elements and growth-promoting compounds. Recent developments indicate that the sludge is a source of vitamin B_{12}, and has been added to mixed foods for cattle and poultry.

The quality of excess activated sludge produced will vary with the food and the extent of oxidation to which the process is carried. In general, about 1 part sludge is produced for each part organic matter destroyed. Prolonged or over-aeration will cause the sludge to partially disperse and digest itself. The amount of air or more precisely oxygen that is necessary to keep the sludge in an active and aerobic condition depends on the oxygen demand of the sludge organisms, the quantity of active sludge, and the amount of food to be utilized. Given sufficient food and sufficient organisms to eat the food, the process seems to be limited only by the rate at which oxygen or air can be dissolved into the mixed liquor. This rate depends on the oxygen deficit, turbulence, bubble size, and temperature and at present is restricted by the physical methods of forcing the air through the diffuser tubers and/or mechanical agitation.

In practice, the excess activated sludge is conditioned with 3–6% $FeCl_3$ and filtered on vacuum filters. This reduces the moisture to about 80% and produces a filter cake which is dried in rotary or spray driers to a moisture content of less than 5%. It is bagged and sold direct as a fertilizer, or to fertilizer manufacturers who use it in mixed fertilizer.

The mechanism of purification of sewage by the activated sludge is twofold i.e., (1) absorption of colloidal and soluble organic matter on the floc with subsequent oxidation by the organisms, and (2) chemical splitting and oxidation of the soluble carbohydrates and proteins to CO_2, H_2O, NH_3, NO_2, NO_3, SO_4, PO_4 and humus. The process of digestion proceeds by hydrolysis, decarboxylation, deaminization and splitting of S and P from the organic molecules before oxidation.

The process is applicable to the treatment of almost any type of organic waste waters which can serve as food for biological growth. It has been applied to cannery wastes, milk products wastes, corn products wastes, and even phenolic wastes. In the treatment of phenolic wastes, a special flora is developed that thrives on phenol as food.

ACTIVATION. 1. The transformation of any material into a more reactive form, or into a form in which it functions more effectively, as in the regeneration of a metallic or inorganic catalyst, the transformation of an enzyme from inactive form to active form, and the treatment of various forms of finely divided silica or carbon to render them more adsorbent.

2. The transfer of a sufficient quantity of energy to an atomic or molecular system to raise it to an excited state in which it can participate in a process not possible when the system is in its ground state.

3. In nuclear physics, the process of inducing radioactivity through neutron bombardment or by other types of radiation.

ACTIVATION ENERGY. 1. The excess energy over the ground state which must be acquired by an atomic or molecular system in order that a particular process may occur. Examples are the energy needed by the molecule to take part in a chemical reaction, by an electron to reach the conduction band in a semiconductor, and by a lattice defect to move to a neighboring site.

In the first example cited, the rate of an elementary chemical reaction can usually be expressed as a product of a function of the concentrations of the participants and of a rate constant. This latter can be written as $A \exp(-E_a/kT)$, where k is the Boltzmann constant; T, the absolute temperature; A, a frequency factor that varies slowly with the activation energy E_a, which appears in the exponential. It is the minimum height of the potential barrier that must be crossed when one follows the reaction coordinate from the reactants to the products. Figure 1 illustrates four typical situations. It is to be noted that it is only in case (**a**) that E_a is equal to the energy of the reaction.

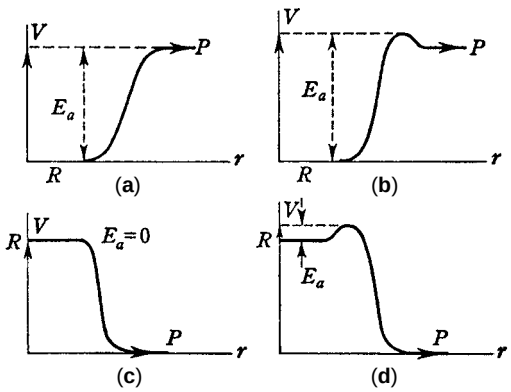

Fig. 1. Activation energy. Variation of the energy along the reaction coordinate for two endothermic (**a**) and (**b**) and two exothermic (**c**) and (**d**) reactions. E_a is the activation energy.

2. If a liquid is regarded as an imperfect solid, the yielding to an applied shear stress takes place at a rate that depends on the frequency with which molecules leave their positions in the imperfect crystal lattice. The variation of this frequency with temperature is described by the energy required for an interchange of a molecule between the lattice and the free volume in the liquid. If this activation energy is linearly dependent on temperature at constant pressure, the slope of the $\log_e \eta : 1/kT$ plot gives the activation energy for liquid flow at low temperatures, where η is viscosity; k, the Boltzmann constant; and T, the absolute temperature.

ACTIVATOR. 1. A substance that renders a material or a system reactive; commonly, a catalyst. 2. A special use of this term occurs in the flotation process, where an activator assists the action of the collector. 3. An impurity atom, present in a solid, that makes possible the effects of luminescence, or markedly increases their efficiency. Examples are copper in zinc sulfide, and thallium in potassium chloride. See also **Enzyme**.

ACTIVE CENTER. Atoms which, by their position on a surface, such as at the apex of a peak, at a step on the surface or a kink in a step, or on the edge or corner of a crystal, share with neighboring atoms an abnormally small portion of their electrostatic field, and therefore have a large residual field available for catalytic activity or for adsorption.

ACTIVE CLOUD. See **Meteorology**.

ACTIVE DEPOSIT. The name given to the radioactive material that is deposited on the surface of any substance placed in the neighborhood of a preparation containing any of the naturally occurring radioactive chains (uranium, thorium, or actinium chains). This deposit results from deposition of the nongaseous products of the gaseous radon nuclides that have escaped from the parent substance. An active deposit can be concentrated on a negatively charged metal wire or surface placed in closed vessels containing the radon. See also **Radioactivity**.

ACTIVE MASS. Mass per unit volume, usually expressed in moles per liter (a concentration factor).

ACTIVE TRANSPORT (Cell). See **Cell (Biology)**.

ACTIVITY COEFFICIENT. A fractional number which when multiplied by the molar concentration of a substance in solution yields the chemical activity. This term provides an approximation of how much interaction exists between molecules at higher concentrations. Activity coefficients and activities are most commonly obtained from measurements of vapor-pressure lowering, freezing-point depression, boiling-point elevation, solubility, and electromotive force. In certain cases, activity coefficients can be estimated theoretically. As commonly used, activity is a relative quantity having unit value in some chosen standard state. Thus, the standard state of unit activity for water, a_w, in aqueous solutions of potassium chloride is pure liquid water at one atmosphere pressure and the given temperature. The standard state for the activity of a solute like potassium chloride is often so defined as to make the ratio of the activity to the concentration of solute approach unity as the concentration decreases to zero.

In general, the activity coefficient of a substance may be defined as the ratio of the effective contribution of the substance to a phenomenon to the actual contribution of the substance to the phenomenon. In the case of gases the effective pressure of a gas is represented by the fugacity f and the actual pressure of the gas by P. The activity coefficient, γ, of the gas is given by

$$\gamma = f/P \tag{1}$$

One method of calculating fugacity, and hence γ, is based on the measured deviation of the volume of a real gas from that of an ideal gas. Consider the case of a pure gas. The free energy F and chemical potential μ changes with pressure according to the equation

$$dF = d\mu = V\, dP. \tag{2}$$

but by definition

$$d\mu = V\, dP = RT\, d\ln f \tag{3}$$

If the gas is ideal, the molal volume V_i is given by

$$V_i = \frac{RT}{P} \tag{4}$$

but for a nonideal gas this is not true. Let the molal volume of the nonideal gas be V_n and define the quantity α by the equation

$$\alpha = V_i - V_n = \frac{RT}{P} - V_n \tag{5}$$

Then V of Eq. (2) is V_n of Eq. (5) and hence from Eq. (5)

$$V = \frac{RT}{P} - \alpha \tag{6}$$

Therefore from Eqs. (2), (3), and (6)

$$RT d\ln f = dF = d\mu = RT D ln P - \alpha dP \tag{7}$$

and

$$RT \ln f = RT \ln P - \int_0^P \alpha dP \tag{8}$$

Thus knowing PVT data for a gas it is possible to calculate *f*. The integral in Eq. (8) can be evaluated graphically by plotting α, the deviation of gas volume from ideality, versus P and finding the area under the curve out to the desired pressure. Also it may be found by mathematically relating α to P by an equation of state, or by using the method of least squares or other acceptable procedure the integral may be evaluated analytically for any value of P. The value of f at the desired value of P may thus be found and consequently the activity coefficient calculated. Other methods are available for the calculation of f and hence of γ, the simplest perhaps being the relationship

$$f = \frac{P^2}{P_i} \tag{9}$$

where P_i is the ideal and P the actual pressure of the gas.

In the case of nonideal solutions, the activity α_A of any component A of the solution can be related to the chemical potential μ_A of that component by the equation

$$\mu_A = \mu_A^{\circ'} + RT \ln \alpha_A \tag{10}$$

$$= \mu_A^{\circ'} + RT \ln \gamma_A X_A \tag{11}$$

where $\mu_A^{\circ'}$ is the chemical potential in the reference state where a_i is unity and is a function of temperature and pressure only, whereas γ_A is a function of temperature pressure and concentration. It is necessary to find the conditions under which γ_A is unity in order to complete its definition. This can be done using two approaches — one using Raoult's law which for solutions composed of two liquid components is approached as $X_A \to 1$; and two using Henry's law which applies to solutions, one component of which may be a gas or a solid and which is approached at $X_A \to 0$. Here X_A represents the mole fraction of component *A*.

For liquid components using Raoult's law

$$\gamma_A \longrightarrow 1 \text{ as } X_A \longrightarrow 1 \tag{12}$$

Since the logarithmic term is zero in Eq. (11) under this limiting condition, $\mu_A^{\circ'}$ is the chemical potential of pure component A at the temperature and pressure under consideration. For ideal solutions the activity coefficients of both components will be unity over the whole range of composition.

The convention using Henry's law is convenient to apply when it is impossible to vary the mole fraction of both components up to unity. Solvent and solute require different conventions for such solutions. As before, the activity of the solvent, usually taken as the component present in the higher concentration, is given by

$$\gamma_A \longrightarrow 1 \text{ as } X_A \longrightarrow 0 \tag{13}$$

Thus, $\mu_A^{\circ'}$ for the solute in Eq. (11) is the chemical potential of the solute in a hypothetical standard state in which the solute at unit concentration has the properties which it has at infinite dilution.

γ_A is the activity coefficient of component A in the solution and is given by the expression

$$\gamma_A = \frac{a_A}{X_A} \tag{14}$$

In Eq. (14) a_A is the activity or in a sense the effective mole fraction of component A in the solution.

The activity a_A of a component A in solution may be found by considering component A as the solvent. Then its activity at any mole fraction is the ratio of the partial pressure of the vapor of A in the solution to the vapor pressure of pure A. If B is the solute, its standard reference state is taken as a hypothetical B with properties which it possesses at infinite dilution.

The equilibrium constant for the process

$$B(\text{gas} \leftrightarrow B(\text{solution}) \tag{15}$$

is

$$K = \frac{a_{\text{solution}}}{a_{\text{gas}}} \tag{16}$$

Since the gas is sufficiently ideal its activity a_{gas} is equivalent to its pressure P_2. Since the solution is far from ideal, the activity a_{solute} of the liquid B is not equal to its mole fraction N_2 in the solution. However,

$$K' = N_2/P_2 \tag{17}$$

and extrapolating a plot of this value versus N_2 to $N_2 = 0$ one obtains the ratio where the solution is ideal. This extrapolated value of K' is the true equilibrium constant K when the activity is equal to the mole fraction

$$K = a_2/P_2 \tag{18}$$

Thus, a_2 can be found. The methods involved in Eqs. (15) through (18) arrive at the activities directly and thus obviate the determination of the activity coefficient. However, from the determined activities and known mole fractions γ can be found as indicated in Eq. (14).

In the case of ions the activities, a_+ and a_- of the positive and negative ions, respectively, are related to the activity, a, of the solute as a whole by the equation

$$a_+^p \times a_-^q \tag{19}$$

and the activity coefficients γ_+ and γ_- of the two charge types of ions are related to the molality, m, of the electrolyte and ion activities a_+ and a_- by the equations

$$\gamma_+ = \frac{a_+}{pm}; \gamma_- = \frac{a_-}{qm} \tag{20}$$

Also the activity coefficient of the electrolyte is given by the equation

$$\gamma = (\gamma_+^p \times \gamma_-^q)^{(1/p+q)} \tag{21}$$

In Eqs. (19), (20) and (21) p and q are numbers of positive and negative ions, respectively, in the molecule of electrolyte. In dilute solutions it is considered that ionic activities are equal for uni-univalent electrolytes, i.e., $\gamma_+ = \gamma_-$.

Consider the case of $BaCl_2$.

$$\gamma = (\gamma_+ \times \gamma^2)^{(1/2+2)} = (\gamma_+ \times \gamma^{\underline{2}})^{1/3} \tag{22}$$

or

$$\gamma^3 = \gamma_+ \gamma^{\underline{2}} \tag{23}$$

also

$$a = a_+ \times a^{\underline{2}} = (m\gamma_+)(2m\gamma_-)^2 \tag{24}$$

$$= 4m^3 \gamma_+ \gamma^{\underline{2}} = 4m^3 \gamma^3 \tag{25}$$

Activity coefficients of ions are determined using electromotive force, freezing point, and solubility measurements or are calculated using the theoretical equation of Debye and Hückel.

The solubility, s, of AgCl can be determined at a given temperature and the activity coefficient γ determined at that temperature from the solubility and the solubility product constant K. Thus

$$K = a_+ a_- = \gamma_+ c_+ \gamma_- c_- \tag{26}$$

where c_+ and c_- are the molar concentrations of the positive silver and negative chloride ions, respectively. The solubility s of the silver chloride is simply $s = c_+ = c_-$. The expression for K is then

$$K = \gamma^2 s^2 \tag{27}$$

and

$$\gamma = \frac{K^{1/2}}{s} \tag{28}$$

By measuring the solubility, s, of the silver chloride in different concentration of added salt and extrapolating the solubilities to zero salt concentration, or better, to zero ionic strength, one obtains the solubility when $\gamma = 1$, and from Eq. (28) K can be found. Then γ can be calculated using this value of K and any measured solubility. Actually, this method is only applicable to sparingly soluble salts. Activity coefficients of ions and of electrolytes can be calculated from the Debye-Hückel equations. For a uni-univalent electrolyte, in water at 25 °C, the equation for the activity coefficient of an electrolyte is

$$\log\gamma = -0.509 z_+ z_- \sqrt{\mu} \tag{29}$$

where z_+ and z_- are the valences of the ion and μ is the ionic strength of the solution, i.e.,

$$\mu = \frac{1}{2} \Sigma c_i z_i^2 \tag{30}$$

where c_i is the concentration and z_i the valence of the ith type of ion.

To illustrate a use of activity coefficients, consider the cell without liquid junction

$$\text{Pt, } H_2(\text{g}); \text{ HCl(m)}; \text{ AgCl, Ag} \tag{31}$$

for which the chemical reaction is

$$\tfrac{1}{2}H_2(g) + AgCl(solid) = HCl\ (molality, m) + Ag(solid). \quad (32)$$

The electromotive force, E, of this cell is given by the equation

$$E = E^\circ - \frac{2.303RT}{nF}\log\frac{a_{HCl}}{P_{H_2}} \quad (33)$$

$$= E^\circ - 0.05915\log m^2\gamma^2$$

where E° is the standard potential of the cell, n is the number of electrons per ion involved in the electrode reaction (here $n = 1$), **F** is the coulombs per faraday, a (equal to $m^2\gamma^2$) is the activity of the electrolyte HCl, P_{H_2} is the pressure (1 atm) and is equal to the activity of the hydrogen gas, and AgCl (solid) and Ag (solid) have unit activities. Transferring the exponents in front of the logarithmic term in Eq. (33), the equation can be written,

$$E = E^\circ - 0.1183\log m - 0.1183\log\gamma \quad (34)$$

which by transposing the log m term to the left of the equation becomes

$$E + 0.1183\log m = E^\circ - 0.1183\log\gamma \quad (35)$$

For extrapolation purposes, the extended form of the Debye-Hückel equation involving the molality of a dilute univalent electrolyte in water at 25 °C is used:

$$\log\gamma = -0.509\sqrt{m} + bm \quad (36)$$

where b is an empirical constant.

Substitution of $\log\gamma$ from Eq. (36) into Eq. (35) gives

$$E + 0.1183\log m - 0.0602m^{1/2} = E^\circ - 0.1183\ bm \quad (37)$$

A plot of the left hand side of Eq. (37) versus m yields a practically straight line, the extrapolation of which to $m = 0$ gives E° the standard potential of the cell. This value of E° together with measured values of E at specified m values can be used to calculate γ for HCl in dilute aqueous solutions at 25° for different m − values. Similar treatment can be applied to other solvents and other solutes at selected temperatures.

Activity coefficients are used in calculation of equilibrium constants, rates of reactions, electrochemical phenomena, and almost all quantities involving solutes or solvents in solution.

EDWARD S. AMIS, University of Arkansas, Fayetteville, Arkansas

ACTIVITY (Radioactivity). The activity of a quantity of radioactive nuclide is defined by the ICRU as $\Delta N/\Delta t$, where N is the number of nuclear transformations that occur in this quantity in time Δt. The symbol Δ preceding the letters N and t denotes that these letters represent quantities that can be deduced only from multiple measurements that involve averaging procedures. The special unit of activity is the curie, defined as exactly 3.7×10^{10} transformations per second. See **Radioactivity**.

ACTIVITY SERIES. Also referred to as the *electromotive series* or the *displacement series*, this is an arrangement of the metals (other elements can be included) in the order of their tendency to react with water and acids, so that each metal displaces from solution those below it in the series and is displaced by those above it. See Table 1. Since the electrode potential of a metal in equilibrium with a solution of its ions cannot be measured directly, the values in the activity series are, in each case, the difference between the electrode potential of the given metal (or element) in equilibrium with a solution of its ions, and that of hydrogen in equilibrium with a solution of its ions. Thus in the table, it will be noted that hydrogen has a value of 0.000. In experimental procedure, the hydrogen electrode is used as the standard with which the electrode potentials of other substances are compared. The theory of displacement plays a major role in electrochemistry and corrosion engineering. See also **Corrosion**; and **Electrochemistry**.

TABLE 1. STANDARD ELECTRODE POTENTIALS (25 °C)

Reaction		Volts
$Li^+ + e^-$	$\rightleftharpoons$ Li	−3.045
$K^+, +e^-$	$\rightleftharpoons$ K	−2.924
$Ba^{2+} + 2e^-$	$\rightleftharpoons$ Ba	−2.90

ACTUATOR (Control System). An actuator is that portion of a final control element in a control system that furnishes the power to change and/or to maintain the valve plug position in response to a signal received from the automatic controller. In some applications, the actuator may position elements other than a valve, such as a louver, damper, or pump speed governor. Actuators may be grouped into several categories: (1) mechanical, (2) pneumatic, (3) hydraulic, and (4) electric. The handwheel on a valve is the simplest form of mechanical actuator. A simple spring-return diaphragm actuator is an example of a pneumatic actuator. Oil-operated cylinders are hydraulic actuators. Motor-operated and solenoid actuators fall into the electrical category. Combination forms include electrohydraulic and electropneumatic actuation. Actuators generally mount directly on the valve body. See **Control System**; and **Valve (Control)**.

The foregoing types of actuators are those generally used in the automation of fluid (gas and liquid) processes common in the petroleum, chemical, and allied manufacturing industries. Although also used to some extent in the discrete-piece manufacturing industries, such as metals fabrication and assembly (as typically found in the automotive, aircraft, electrical, and mechanical equipment manufacturing industries, among others), the final controlling actuators frequently take other forms, such as robots and mechanized placement devices. See **Automation**.

ACUTE CORONARY SYNDROME. See **Coronary Thrombosis**.

ACUTE (Medical). Having a rapid onset, severe symptoms, and a relatively short duration; not chronic.

ACUTE MYOCARDIAL INFRACTION (AMI). See **Coronary Thrombosis**.

ACYL. An organic radical of the general formula, RCO−. These radicals are also called acid radicals, because they are often produced from organic acids by loss of a hydroxyl group. Typical acyl radicals are acetyl, CH_3CO-, benzyl, C_6H_5CO-, etc.

ACYLATION. A reaction or process whereby an acyl radical, such as acetyl, benzoyl, etc., is introduced into an organic compound. Reagents often used for acylation are the acid anhydride, acid chloride, or the acid of the particular acyl radical to be introduced into the compound.

ADAMANTINE COMPOUND. A compound having in its crystal structure an arrangement of atoms essentially that of diamond, in which every atom is linked to its four neighbors mainly by covalent bonds. An example is zinc sulfide, but it is to be noted that the eight electrons involved in forming the four bonds are not provided equally by the zinc and sulfur

atoms, the sulfur yielding its six valence electrons, and the zinc, two. This is the structure of typical semiconductors, e.g., silicon and germanium.

ADAMS, ROGER (1889–1971). An American chemist, born in Boston; graduated from Harvard, where he taught chemistry for some years. After studying in Germany, he move to the University of Illinois in 1916, where he later became chairman of the department of chemistry (1926–1954). During his prolific career, he made this department one of the best in the country, and strongly influenced the development of industrial chemical research in the U.S. His executive and creative ability made him an outstanding figure as a teacher, innovator, and administrator. Among his research contributions were development of platinum-hydrogenation catalysts, and structural determinations of chaulmoogric acid, gossypol, alkaloids, and marijuana. He held many important offices, including president of the ACS and AAS, and was a recipient of the Priestley medal.

ADANSON, MICHEL (1727–1806). Born in Aix-en-Provence, Michel Adanson received as a boy a gift that fostered his scientific vocation: a microscope, offered by John Tuberville Needham, famous for his views on spontaneous generation. Adanson soon became a keen observer; he was more of a manual worker than a theoretician. By the age of 19, he had already learned to describe more than 4000 species of animals and plants. After visiting the Azores and Canary Islands in 1748 on behalf of Compagnie des Indes, he took part in a four-year expedition to Senegal, at the age of 22. He discovered a prodigious number of new species, among them the baobab, a giant tree later named *Adansonia* in his honor. Adanson was curious about topography, meteorology and anthropology. Influenced by Rousseau's ideas on nature, he enjoyed learning from the locals. Inspired by African languages, he even devised his own Esperanto. See also **Needham, John Turberville (1713–1781)**.

Adanson made a proposal to the Académie des Sciences for an ambitious multivolume encyclopedia based on his collections. Refusing to work on a smaller scale, he chose to live as a recluse in Paris, writing while he sat on the floor, a habit he had brought back from Africa. Opposed to Linnaeus's system, Adanson attempted to catalogue living beings according to their natural series. Failing to understand the subordination of characters, he relied on 65 different characters, each forming a system! The botanist described 58 natural families of flowers. Adanson became extremely poor after the French Revolution (1789–1799) and he developed a fatal illness. His herbarium of 30 000 specimens is kept at the Muséum National d'Histoire Naturelle. See also **Linnaeus, Carl (Linné) (1707–1778)**; and **Plant Sciences (The History)**.

OLIVIER LAGUEUX, Yale University, New Haven, CT

ADAPTATION (Ecology). The process of modification of a living organism as it adjusts to the conditions of its environment. Also, an inherited characteristic that enables the organism to meet certain environmental conditions.

All living things are adapted for a mode of life characteristic of their kind, under equally characteristic environmental conditions. They receive from previous generations a heritage that fits them for this mode of life, and all characters in the hereditary complex that are of definite use are adaptive. Wings, for example, are essential flight adaptation, and fins or other similar appendages are commonly found as adaptations for swimming.

Regardless of its adaptive heritage, however, each individual encounters some fluctuations in its environment to which it must adjust itself. The resulting changes in its body are adaptive, no less than its inherited structures. They are the acquired characters of biological literature, and have also been called individual adaptations. Human beings commonly experience two fine examples of this kind of adaptation in the calluses formed by the skin in response to friction, and the deposition of pigment, or tanning, as a protection against excessive ultraviolet light. A less evident result of exposure to ultraviolet light is a protective thickening of the epidermis, probably as important as the accompanying increase in pigmentation. It is interesting to note that the dark-skinned natives of central Africa, for example, do not sunburn as easily as persons with light-colored skin.

Although of different species, it is interesting to note that animals and plants from different parts of the earth often appear to be related as the result of certain adaptations to a given regional environment. The resemblance of Cacti, which are prevalent in the deserts of the New World, but unknown in the deserts of Africa, nevertheless look very much like the euphorbias found in Africa. Botanically they are unalike. The cava found in the Argentine pampas is related to the guinea pig, although its resemblance to the jackrabbit of similar grassland environment in North America is indeed striking. Adaptation of this type is referred to as *convergent adaptation*.

These adaptations have long been recognized, bringing about a series of generalizations that usually apply with few exceptions. For example, Gloger's rule states that cold dry climates encourage light colorations in animals whereas warm and moist climates encourage darker colors. Allen's rule states that parts protruding from the body tend to be shorter in colder climates (long noses are not found among the natives of cold central Asia, for example). Bergmann's rule states that individuals tend to be smaller in warmer climates.

ADAPTATION LUMINANCE. The average luminance (or brightness) of those objects and surfaces in the immediate vicinity of an observer. Also called *adaptation brightness, adaptation level, adaptation illuminance*. The adaptation luminance has a marked influence on an observer's estimate of the visual range because, along with the visual angle of the object under observation, it determines the observer's threshold contrast. High adaptation luminance tends to produce a high threshold contrast, thus reducing the estimated visual range. This effect of the adaptation luminance is to be distinguished from the influence of background luminance.

ADAPTIVE CONTROL. A closed-loop control system in which system performance is monitored in relation to what might be termed an index of performance. Adaptive control is a sophisticated improvement, in most cases, of what might be called conventional control systems which employ feedback and sometimes feedforward concepts. Prior to considering adaptive control, some readers may wish to turn to the entry on **Control System (Automatic)** for a fundamental review of the principles of automatic control. Reduced to basics, adaptive control is, in essence, a superimposition of an additional measurement and decision-making system for "controlling the controller." Thus, adaptive systems are sometimes called "self-tuning" controllers. An example is in order to illustrate why this additional control system complication is sometimes needed.

Consider a heat exchanger that uses saturated steam to heat water that flows through its tube bundle. A simple controller will sense the outlet water temperature and attempt to position the steam valve so that the actual water temperature will equal the desired water temperature. This system, however, will not accommodate the nonlinearities in the steam valve and possible changes in stream pressure. A *cascade controller* is a partial approach to adaptive control and is described in entry on **Cascade Control**. In our heat exchanger example, a cascade control system will use a slower-acting temperature controller, not to directly control the steam supply valve, but rather to adjust the set point of a faster-acting steam controller. In this example, one controller is superimposed over another controller.

Unfortunately, a fixed-parameter temperature controller encounters difficulties because of the nonlinear, time-varying behavior of the process. For example, a change in water flow rate changes the effective delay time and heat transfer characteristics of the process. Gradual fouling of the heat exchanger tubes also changes the process dynamics over time. As a result, good control performance at one operating condition can give way to very poor performance (overdamped or unstable response) at another operating condition.

In adaptive control, a method must be provided for the system to change parameters automatically within the closed loop. Auxiliary control variables are measured and evaluated with the objective of modifying the principal control functions so that selected control system performance criteria or indexes can be better realized. Adaptive control is similar to optimal control, in that various parameters are changed as a function of time. Adaptive control differs from optimal control in that parameters in the model of the process are to be evaluated on-line. Thus, adaptive control *combines control with the solution* of the identification problem. The resulting control may or may not be optimal. In particular, adaptive control is useful in cases where the process dynamics are not fully defined or change with time.

Professional thinking in terms of adaptive control of processes and machines was revised, particularly during the late 1980s as the result of introduction of microprocessors and minicomputers to the hardware of

automatic control. Adaptive control is part of a family of concepts that fall under the general umbrella term of *expert systems* or *smart controllers*. Some of the rudimentary concepts of artificial intelligence (AI) may be involved. See entry on **Artificial Intelligence**.

Fundamental to the consideration of adaptive control are: (1) sufficient betterment in control performance must be obtainable to justify the additional (often extensive) computation required, (2) the state variables or the model parameters that are to be evaluated must be observable directly or indirectly, (3) where parameters are not directly computable from measured signals, there must be sufficient variation on inputs to permit the estimation of these parameters by their influence, and (4) the dynamics of the system must be such that the parameters can be evaluated in a time that is reasonable based upon their rate of change. The fundamental operation of adaptive control is shown in Fig. 1.

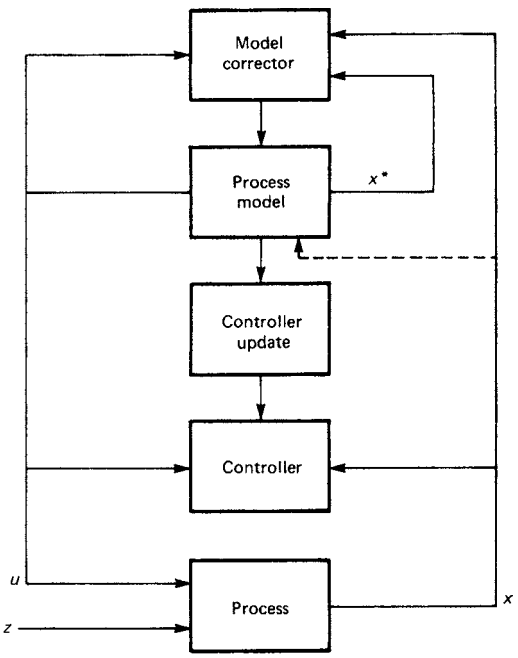

Fig. 1. Hierarchical control structure (x, state factor, x^*, new state factor, u, control factor; z, z-transform.)

The basic concepts can be demonstrated by use of a model-adaptive system, such as shown in Fig. 2. In the model-adaptive system, the controlled variable c is compared with the model output c_d. The difference in the two signals is a measure of performance or performance error. Control parameters are adjusted as a function of the performance error to bring the controlled variable to the desired value. One advantage of this type of system is the independent operation of the adaptive and main control loops. Operation of the main control loop can be maintained in event of a failure in the adaptive loop. The complexity of adaptive systems is a major disadvantage in many practical applications. Because of the feedback, which is a part of all closed-loop systems, there is a problem of stability against oscillation. Various forms of Nyquist criteria may be applied in the design of closed-loop systems to ensure satisfactory performance from the standpoint of stability.

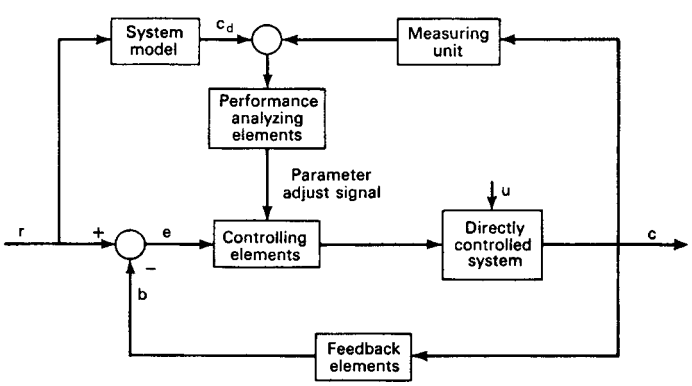

Fig. 2. Model adaptive system.

The adaptive concept as applied to a 2-axis milling machine is shown in Fig. 3. The cutter velocity signal ω and torque signal τ are used in a simple multiplier to obtain a signal proportional to the power delivered to the workpiece by the cutter. From a previously determined relationship between cutter power and workpiece feed rate (axis velocity), a model signal that is useful in determining maximum cutter deflection is obtained. This signal is used to modify position-loop command (axis velocity) for optimum conditions of stock removal. The adaptive control loop for a milling machine is shown in Fig. 4.

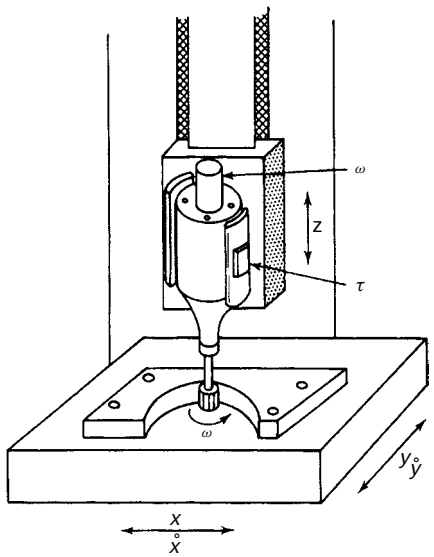

Fig. 3. Variables involved in adaptive control system for a 2-axis milling machine.

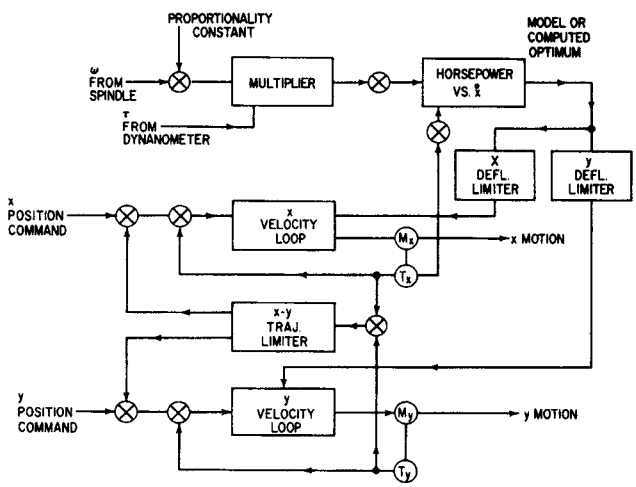

Fig. 4. Adaptive control system for milling machine.

Adaptive control as applied to the heat balance problem of a semibatch reactor is shown in Fig. 5. Reactant gas A is added to liquid B to make liquid product C, also with the production of liquid by-product D. For maximum yield of C, it is desirable to operate the reactor near the batch freeze point. The setpoint of the temperature control loop must be adjusted to follow the freeze point. The freeze point increases with changing chemical composition during the batch. As shown, an analog computer is used to compute the incoming flow and thus determines the freeze point of the batch system to be used as the setpoint of the temperature controller. A different approach to the problem is shown in Fig. 6. This system does not depend upon external data. Rather, the adaptive control signal that controls the primary loop gain is obtained from analysis of the error signal.

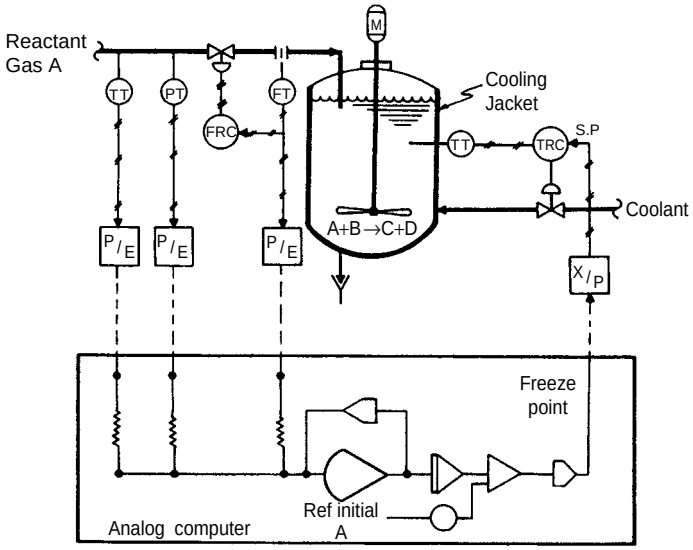

Fig. 5. An adaptive control approach to heat-balance problem of a semibatch reactor.

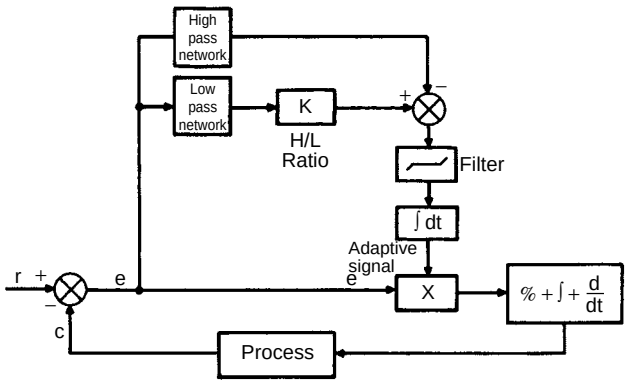

Fig. 6. Adaptive control approach to heat-balance problem based upon analysis of error signal.

The signal is separated into high and low components, multiplied by a ratio factor, combined, and then passed through a filtering and integrating network. A system of this type may be designed for universal purposes and thus the performance characteristics and reliability may not be expected to compete with the programmed controller, inasmuch as the latter is specifically designed for the particular process.

ADAPTIVE CONTROL SYSTEM. A control system that continuously monitors the dynamic response of the controlled system and automatically adjusts critical system parameters to satisfy pre-assigned response criteria, thus producing the same response over a wide range of environmental conditions. See also **Adaptive Control**.

ADAPTIVE GRID. See **Meteorology**.

ADAPTIVE MULTI-RATE (AMR). See **Data Compression**.

ADAPTIVE OBSERVATIONAL NETWORK. An observational network in which the location and timing of measurements of atmospheric properties are changed on a daily basis in order to minimize some measure of forecast error.

To achieve this aim, atmospheric measurements must adapt to the flow observed on a particular day. For example, in midlatitude regions, enhanced atmospheric measurements in regions of large horizontal temperature gradients can lead to a significant reduction in forecast error. As these regions of strong baroclinicity move from one day to the next, the locations of enhanced measurements should also move.

AMS

ADAPTIVE OBSERVATIONS. Observational data obtained specifically to improve model initial conditions for a numerical forecast of a selected weather feature, or to optimize a measure of forecast outcome (e.g., error). Also called *targeted observations*.

Guidance for selecting adaptive observations can be obtained from model-based products, such as singular vectors from adjoint models or ensemble forecasts, which are used to estimate where initial condition error has the greatest impact on the forecast measure. Adaptive observations can be obtained from in-situ platforms such as dropsonde aircraft, or by direction of remote sensors including satellite or radar instruments.

AMS

A/D CONVERTER. Abbreviation for analog-to-digital converter, an electronic device for quantifying a (typically) continuous-time voltage signal to a numeric discrete-sample sequence. See also **Analog-to-Digital Converter**.

ADDAX *(Mammalia, Artiodactyla).* A screw-horned antelope, *Addax nasomaculatus*, of northern Africa and Arabia.

Built like a reindeer, these animals have a short neck, long rump, medium-long sturdy legs, and a straight back, with the withers slightly higher. The rather large head has a considerable tuft on the forehead, especially in old males. The eyes are small and the preorbital glands are not visible. The moderately thin horns, which slant backward and up and slightly to the sides in large, flat spirals are almost round in a crosscut. They have low, flat hooves with flat plantars (sole of foot) which are not sectioned into balls. The round, thin tail has a short tassel on the end. The winter coat is longer and rougher than the summer coat.

Like the scimitar-horned oryx and the North African hartebeest, the addax was kept semi-tame in large numbers in ancient Egypt. According to pictures from this time, addax stood in stables like goats. They were fed out of troughs, led on a bridle, and were probably slaughtered for cult purposes. Keepers developed special procedures for protection against the pointed horns of the animal.

Since 1900 the addax has disappeared from Egypt, and even before that time it had been exterminated in the north of Algeria, Tunisia, Libya, and surrounding environs. Formerly, there were herds of hundreds and thousands. They may go for weeks and even months without water. Like camels, the walls of addax stomachs are said to be transformed into alveolar reservoirs for liquids. The animals are active in the morning, evening, and night. In order to protect themselves against strong winds and solar radiation, they dig holes with their front legs and lie down in them.

Although in the past, addax antelopes were commonly kept in zoos, this is now rare. Thus, the breeding groups in a comparatively few zoos are important to the ultimate preservation of the species. In captivity, the addax achieves a maximum age of about 18 years.

ADDER (Computer System). A digital circuit that provides the sum of two or more input numbers as an output. A one-bit binary adder is illustrated in Fig. 1. In this diagram, *A* and *B* are the input bits and *C* and

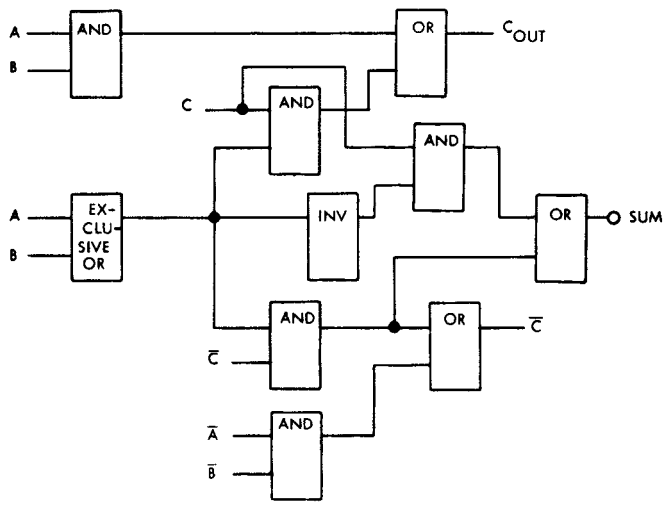

Fig. 1. Binary adder.

$\overline{C}$ are the carry and no-carry bits from the previous position. There are both serial and parallel adders. In a serial adder, only one adder position is required and the bits to be added are sequentially gated to the input. See also **Gate (Computer System)**. The carry or no carry from the prior position is remembered and provided as an input along with the bits from the next position. In a parallel adder, all the bits are added simultaneously with the carry or no carry from the lower-order position propagated to the higher position. In a parallel adder, there may be a delay due to the carry propagation time. See also **Half-Adder**.

An adder may perform subtraction as well as the addition of two numbers. Generally, this is effected by complementing one of the numbers and then adding the two factors. The following is an example of a two's-complement binary-subtraction operation.

(a)		0110	+6	(True)
	(+)	1010	−6	(Complement)
		10000	0	(True)
(b)		0101	+5	(True)
	(+)	1010	−6	(Complement)
		1111	−1	(Complement)
(c)		1111	(Complement) = −0001	(True)

The two's complement of a binary number is obtained by replacing all **1**'s with **0**'s, all **0**'s with **1**'s, and adding **1** to the units position. In (A) above, **6** is subtracted from **6**, and the result is all **0**'s; the carry implies that the answer is in true form. In (B), **6** is subtracted from **5**, and the result is all **1**'s with no carry. The no carry indicates the result is in complement form and that the result must be re-complemented as shown in (C).

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ADDISON'S DISEASE. A disease caused by malfunction of the adrenal glands. It is characterized by a bronze color of the skin, prostration, anemia, disturbance of electrolyte metabolism, and diarrhea. Many cases are believed to result from an autoimmune disorder, i.e., an immune reaction by the body against some stimulus naturally present within itself. Sometimes it is caused by involvement of the glands by tuberculosis and other infections, metastatic tumors, or amyloidosis, but the principal cause is primary adrenal failure.

Success in treating the disease in recent years has increased because of the availability of cortisol or cortisone and also because of supplementation with a sodium-retaining hormone to maintain the salt level in the body. The availability of purified hormones has simplified the treatment, where often each symptom can be alleviated with a corresponding hormone. For example, there is a specific hormone responsible for maintaining the water and salt balance of the body. Past practice has also included taking meals high in starch at fairly frequent intervals.

Studies by Sadeghi-Nejad and Senior have shown that, in children, *adrenoleukodystrophy* is an additional, genetically determined, rare cause of Addison's disease. One form of adrenoleukodystrophy in infants is transmitted as an autosomal recessive trait; the disorder in older patients is sex-linked. Adrenoleukodystrophy is a peroxisomal dysfunction, resulting in the impaired oxidation of very-long-chain saturated fatty acids, mainly hexacosanoic acid. These fatty acids accumulate in the brain, adrenal glands, and other organs and are believed to be responsible for the clinical manifestations of the disease.

The neurological features of adrenoleukodystrophy include dementia and deterioration of vision, speech, and gait.

See **Adrenal Disease**.

ADDITION. A fundamental operation for combining mathematical terms. The symbol + is used to denote the operation. To perform the operation of addition of two quantities x and y, it is necessary to identify like terms. If x and y are polynomials in z, then like terms are the terms in x and y containing z to the same power. For complex numbers, $x = a + ib$, $y = c + id$, $x + y = (a + b) + i(b + d)$. For fractions to have like terms, one must use common denominators.

$$\frac{a}{b} + \frac{c}{d} = \frac{ad}{bd} + \frac{cd}{bd} = \frac{ad + cb}{bd}.$$

Frequently, common factors can be cancelled in the numerator and denominator, e.g.,

$$\frac{1}{3} + \frac{1}{6} = \frac{6 + 3}{18} = \frac{9}{18} = \frac{1}{2}$$

Addition consists of finding the algebraic sum of like terms. Eventually, one must use the same process as in arithmetic: determine the numerical value of an addition by the addition tables for the base in use.

DONALD R. HODGE, Alexandria, VA

ADDITIVE COLOR PROCESS. An early system of color imagery in which the color synthesis is obtained by the addition of colors one to another in the form of light rather than as colorants. This color addition may take place (1) by the simultaneous projection of two or more (usually three) color images onto a screen, (2) by the projection of the color images in rapid succession onto a screen or (3) by viewing minutely divided juxtaposed color images.

In the case of a three-color process, three-color records are made from the subject recording, in terms of silver densities, the relative amounts of red, green, and blue present in various areas of the subject.

When the additive synthesis is to be made by simultaneous projection, positives are made from the color separation negatives and projected with a triple lantern onto a screen through red, green, and blue filters. The registered color images give all colors of the subject due to simple color addition, red plus green making yellow, red plus blue appearing magenta, etc.

When the additive synthesis is made by successive viewing, the same three-color images must be flashed onto the screen in such rapid succession that the individual red, green, and blue images are not apparent. Simple color addition is again obtained but this time use is made of the persistence of vision to "mix" the colors. See Fig. 1.

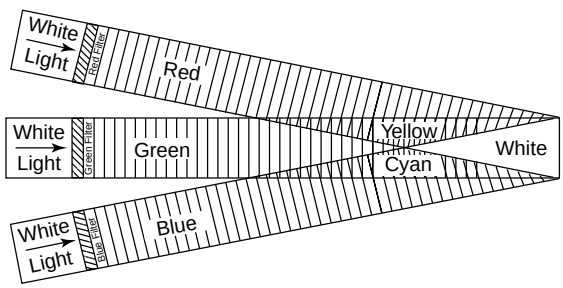

Fig. 1. Mechanism of color addition.

The third type of additive synthesis makes use of the fact that small dots of different colors, when viewed from such a distance that they are no longer individually visible, form a single color by simple color addition. The three-color images in this type of process are generally side by side in the space normally occupied by a single image. The red record image will be composed of a number of red dots or markings of differing density which, in total, will compose the red record image. Alongside the red markings will be green and blue markings, without any overlapping. When viewed at such a distance that the colored markings are at, or below, the limit of visual resolution, the color sensation from any given area will be the integrated color of the markings comprising the area — an additive color mixture.

ADDITIVE (Fuel). See **Petroleum**.

ADDITIVES (FOOD). See **Food Additives**.

ADDRESS (Computer System). An identification, represented by a name, label, or number, for a digital computer register, device, or location in storage. Addresses are also a part of an instruction word along with commands, tags, and other symbols. The part of an instruction that specifies an operand for the instruction may be an address.

Absolute address or specific address indicates the exact physical storage location where the referenced operand is to be found or stored in the actual machine code address numbering system.

Direct address or first-level address indicates the location where the referenced operand is to be found or stored with no reference to an index register.

Indirect address or *second-level* address in a computer instruction indicates a location where the address of the referenced operand is to be found. In some computers, the machine address indicated can in itself be indirect. Such multiple levels of addressing are terminated either by prior control or by a termination symbol.

Machine address is an absolute, direct, unindexed address expressed as such, or resulting after indexing and other processing have been completed.

Symbolic address is a label, alphabetic or alphameric, used to specify a storage location in the context of a particular program. Sometimes programs may be written using symbolic addresses in some convenient code, which then are translated into absolute addresses by an assembly program.

Base address permits derivation of an absolute address from a relative address.

Effective address is derived from applying specific indexing or indirect addressing rules to a specified address.

Four-plus-one address incorporates four operand addresses and a control address.

Immediate address incorporates the value of the operand in the address portion instead of the address of the operand.

N-level address is a multilevel address in which N levels of addressing are specified.

One-level address directly indicates the location of an instruction.

One-plus-one address contains two address portions. One address may indicate the operand required in the operation. The other may indicate the following instruction to be executed.

Relative address is the numerical difference between a desired address and a known reference address.

Three-plus-one address incorporates an operation code, three operand address parts, and a control address.

Zero-level address enables immediate use of the operand.

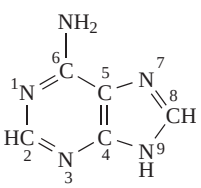
ADDRESS RESOLUTION PROTOCOL (ARP). See **Transmission Control Protocol (TCP)/Internet Protocol (IP) Suite**.

ADENINE. Adenine [CAS: 73-24-5] is a prominent member of the family of naturally occurring purines (see Structure 1). Adenine occurs not only in ribonucleic acids (RNA), and deoxyribonucleic acids (DNA), but in nucleosides, such as adenosine, and nucleotides, such as adenylic acid, which may be linked with enzymatic functions quite apart from nucleic acids. Adenine, in the form of its ribonucleotide, is produced in mammals and fowls endogenously from smaller molecules and no nutritional essentiality is ascribed to it. In the nucleosides, nucleotides, and nucleic acids, the attachment or the sugar moiety is at position 9.

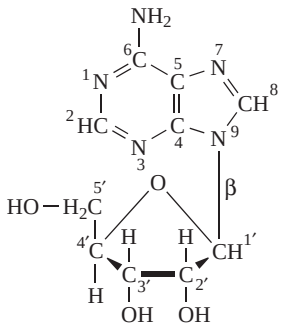


(1)

The purines and pyrimidines absorb ultraviolet light readily, with absorption peaks at characteristic frequencies. This has aided in their identification and quantitative determination.

ADENOMA. A benign tumor consisting of an encapsulated overgrowth of epithelial cells of a glandular structure. Adenomata may occur in the endocrine glands, the gastro-intestinal tract, the respiratory system, the breast, and wherever glandular epithelium occurs. A malignant adenoma is referred to as an *adenocarcinoma*.

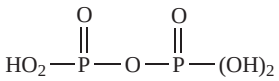
ADENOSINE. Adenosine [CAS: 58-61-7] is an important nucleoside composed of adenine and ribose. White, crystalline, odorless powder, mild, saline, or bitter taste, Mp 229C, quite soluble in hot water, practically insoluble in alcohol. Formed by isolation following hydrolysis of yeast nucleic acid. The upper portion of Structure 1 represents the adenine moiety, and the lower portion of the pentose, D-ribose.



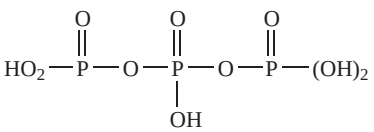
(1)

ADENOSINE DI-AND TRIPHOSPHATE. See also **Carbohydrates**; **Phosphorylation (Oxidative)**; and **Phosphorylation (Photosynthetic)**.

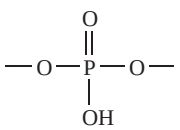
ADENOSINE PHOSPHATES. The adenosine phosphates include *adenylic acid* [CAS: 84-21-9], (adenosine monophosphate, AMP) in which adenosine is esterified with phosphoric acid at the 5′-position; *adenosine diphosphate* (ADP) in which esterification at the same position is with pyrophosphoric acid,



and *adenosine triphosphate* (ATP) in which three phosphate residues



are attached at the 5′-position. Adenosine-3′-phosphate is an isomer of adenylic acid, and adenosine-2′,3′-phosphate is esterified in two positions with the same molecules of phosphoric acid and contains the radical.



ADHARA (∈ Canis Majoris). Ranking twenty-second in apparent brightness among the stars, Adhara has a true brightness value of 8,000 as compared with unity for the sun. Adhara is a blue-white, spectral type B star and is located in the constellation Canis Majoris. Estimated distance from the earth is 600 light years. See also **Constellations**.

ADHESION EFFICIENCY. See **Meteorology**.

ADHESION (Physics). The terms adhesion and cohesion designate intermolecular forces holding matter together. The tendency of matter to hold itself together or to cling to other matter is one of its most characteristic properties. Adhesion and cohesion are merely different aspects of the same phenomenon, which is apparently of the nature of an intermolecular attraction. One speaks of cohesion as an interaction between

adjacent parts of the same body and as acting throughout the interior of its substance, while adhesion refers to a similar interaction between the closely contiguous surfaces of adjacent bodies.

In the case of solids, the experimental study of adhesion and cohesion, in which two solids are brought into intimate contact, can depend on the nature of adsorbed gases. For clean surfaces it is necessary to carry out the experiments in "ultra high vacuum" at pressures better than 10^{-10} torr.

There is reason to believe that, as two neutral molecules or atoms approach each other, their mutual potential energy reaches a minimum value at a certain equilibrium distance, so that work would be necessary, either to push them closer or to pull them farther apart, because of forces which are probably electrical. See **Least Energy Principle**. The distribution of molecules, ions, or atoms in a solid is determined by this type of equilibrium, and the regular spacing of crystal structure and the architecture of the molecule itself are dependent upon it. Any force tending to diminish the equilibrium distance meets with the rapidly increasing reaction of compressive elasticity, while any force tending to increase it is opposed by cohesion, which increases at first and then rapidly diminishes toward zero as the point of fracture is reached.

The behavior of bodies that are aggregates of crystals or of fibers is complicated by the friction and the adhesion of the adjacent particles, so that the ultimate strength of a material is not a safe measure of its true cohesion. A filament of spun quartz may be much stronger when freshly drawn than later when crystallization replaces its initial cohesion by the adhesion between separate crystals; and yarn is not nearly so strong as the cotton or wool fiber composing it.

Adhesion increases with closeness of contact. This explains why one must bear down with a pencil to make a mark on paper, why fine dust adheres more firmly than coarse sand, and why a liquid or a gum usually sticks to a solid better than another solid does.

Cohesion in liquids is usually less, and in gases it is always much less, than in solids. Aside from the pressure in liquids due to external causes, there is presumably a very great internal or intrinsic pressure, due to intermolecular attraction, but not capable of direct measurement by means at our disposal. The clearest evidences of its existence are the work required for thermal expansion and the phenomenon of surface tension.

Very practical aspects of materials adhesion are encountered in the bulk materials processing industries. Two common terms are used—*arching* and *flushing*. Both properties are associated with what is known as the *angle of repose*. See also **Repose (Angle of)**. Many materials, such as lampblack, activated carbon, zinc oxide, titanium oxide, fine soda ash, and hydrated lime, among many others, tend to arch when placed in containing vessels such as hoppers. Materials above the arch are held back and consequently interfere with the unloading of the hopper and thus prevent uniformity of solids-flow, as required by most continuous processes. Arching is best overcome by keeping the individual solid particles constantly in motion. Electric vibrators are commonly used for this purpose. Very few materials are crushed or pulverized so well that all particles are of approximately equal size. In the absence of hopper vibration, the smaller particles and fines tend to segregate and roughly collect in a center cone, while the larger particles roll to the side. Thus, the fines drop out first, while the larger particles discharge later, the end result of which is formation of an arch. Flushing is caused by the sudden breaking of an arch or otherwise clogged state. Thus, vibration also helps to eliminate flushing.

ADHESION (Work of). The work of adhesion W_{AB} between two liquids A and B is the increase in free surface energy on separating 1 cm^2 of interface AB

$$W_{AB} = \gamma_A + \gamma_B - \gamma_{AB}$$

where γ_A and γ_B are the surface tensions of A and B respectively against their vapors, and γ_{AB} is the interfacial tension. For a solid-liquid interface the work of adhesion W_{SL} is defined as the work required to separate 1 cm^2 of interface in a vacuum to give a naked solid surface

$$W_{SL} = \gamma_S + \gamma_L - \gamma_{SL}$$

where γ_S and γ_L are the surface tensions measured in a vacuum.

It may be shown that

$$W_{SL} = \gamma_S - \gamma_{SV0} + \gamma_L(1 + \cos\theta_E)$$

where γ_{SV_o} is the surface tension of the solid covered by an absorbed film of liquid in equilibrium with the vapor, and θ_E is the equilibrium contact angle.

ADHESIVES. An *adhesive* is a material capable of holding together solid materials by means of surface attachment. *Adhesion* is the physical attraction of the surface of one material for the surface of another. An *adherend* is the solid material to which the adhesive adheres and the *adhesive bond* or *adhesive joint* is the assembly made by joining adherends together by means of an adhesive. *Practical adhesion* is the physical strength of an adhesive bond. It primarily depends on the forces of adhesion, but its magnitude is determined by the physical properties of the adhesive and the adherend, as well as the engineering of the adhesive bond.

The *interphase* is the volume of material in which the properties of one substance gradually change into the properties of another. The interphase is useful for describing the properties of an adhesive bond. The *interface*, contained within the interphase, is the plane of contact between the surface of one material and the surface of another. Except in certain special cases, the interface is imaginary. It is useful in describing surface energetics.

Theories of Adhesion

There is no unifying theory of adhesion describing the relationship between practical adhesion and the basic intermolecular and interatomic interactions which take place between the adhesive and the adherend either at the interface or within the interphase. The existing adhesion theories are, for the most part, rationalizations of observed phenomena, although in some cases, predictions regarding the relative ranking of practical adhesion can actually be made.

The diffusion theory of adhesion is mostly applied to polymers. It assumes mutual solubility of the adherend and adhesive to form an interphase.

The basis of the electrostatic theory of adhesion is the differences in the electronegativities of adhering materials which leads to a transfer of charge between the materials in contact. The attraction of the charges is considered the source of adhesion.

The surface energetics and wettability theory of adhesion is concerned with the effect of intermolecular and interatomic forces on the surface energies of the adhesive and the adherend and the interfacial energy between the two.

A practical adhesion can be enhanced if the adhesive is applied to a surface which is microscopically rough.

The various adhesion theories can be used to formulate guidelines for good adhesion:

1. An adhesive should possess a liquid surface tension that is less than the critical wetting tension of the adherend's surface.
2. The adherend should be mechanically rough enough so that the asperities on the surface are on the order of, or less than, one micrometer in size.
3. The adhesive's viscosity and application conditions should be such that the asperities on the adherend's surface are completely wetted.
4. If an adverse environment is expected, covalent bonding capabilities at the interface should be provided.

For good adhesion, the adhesive and the adherend should, if possible, display mutual solubility to the extent that both diffuse into one another, providing an interphasal zone.

Advantages and Disadvantages

In comparison to other methods of joining, adhesives provide several advantages. First, a properly applied adhesive provides a joint having a more uniform stress distribution under load than a mechanical fastener which requires a hole in the adherend. Second, adhesives provide the ability to bond dissimilar materials such as metals without problems such as galvanic corrosion. Third, using an adhesive to make an assembly increases fatigue resistance. Fourth, adhesive joints can be made of heat- or shock-sensitive materials. Fifth, adhesive joining can bond and seal simultaneously. Sixth, use of an adhesive to form an assembly usually results in a weight reduction in comparison to mechanical fasteners since

adhesives, for the most part, have densities which are substantially less than that of metals.

There are some limitations in using adhesives to form assemblies. The major limitation is that the adhesive joint is formed by means of surface attachment and is, therefore, sensitive to the substrate surface condition. Another limitation of adhesive bonding is the lack of a nondestructive quality control procedure. Finally, adhesive joining is still somewhat limited because most designers of assemblies are simply not familiar with the engineering characteristics of adhesives.

Mechanical Tests

The three principal forces to which adhesive bonds are subjected are a shear force in which one adherend is forced past the other, peeling in which at least one of the adherends is flexible enough to be bent away from the adhesive bond, and cleavage force. The cleavage force is very similar to the peeling force, but the former applies when the adherends are nondeformable and the latter when the adherends are deformable. Appropriate mechanical testing of these forces are used. Fracture mechanics tests are also typically used for structural adhesives.

Because the load-bearing capabilities of an adhesive are dependent upon the adherend material, the loading rate, temperature, and design of the adhesive joint, wide ranges of performance are listed.

Uses

A structural adhesive is a resin system, usually a thermoset, that is used to bond high strength materials in such a way that the bonded joint is able to bear a load in excess of 6.9 MPa (1000 psi) at room temperature. Structural adhesives are the strongest form of adhesive and are meant to hold loads permanently. They exist in a number of forms. The most common form is the two-part adhesive, widely available as a consumer product. The next most familiar is that which is obtained as a room temperature curing liquid. Less common are primer—liquid adhesive combinations which cure at room temperature. Structural adhesive pastes which cure at 120 °C are widely available in the industrial market.

Structural adhesives are formulated from epoxy resins, phenolic resins, acrylic monomers and resins, high temperature-resistant resins (e.g., polyimides), and urethanes. Structural adhesive resins are often modified by elastomers.

Natural-product-based structural adhesives include protein-based adhesives, starch-based adhesives, and cellulosics.

A pressure-sensitive adhesive, a material which adheres with no more than applied finger pressure, is aggressively and permanently tacky. It requires no activation other than the finger pressure, exerts a strong holding force, and should be removable from a smooth surface without leaving a residue. Pressure-sensitive adhesives are most widely used in the form of adhesive tapes.

Hot-melt adhesives are 100% nonvolatile thermoplastic materials that can be heated to a melt and then applied as a liquid to an adherend. The bond is formed when the adhesive resolidifies. The oldest example of a hot-melt adhesive is sealing wax.

Solvent-based adhesives, as the name implies, are materials that are formed by solution of a high molecular weight polymer in an appropriate solvent. Solvent-based adhesives are usually elastomer-based and formulated in a manner similar to pressure-sensitive adhesives.

The most widely used emulsion-based adhesive is that based upon poly(vinyl acetate)–poly(vinyl alcohol) copolymers formed by free-radical polymerization in an emulsion system. Poly(vinyl alcohol) is typically formed by hydrolysis of the poly(vinyl acetate). This is also known as "white glue."

An excellent review of "Adhesive Bonding" is contained in the *Modern Plastic Encyclopedia*, issued annually by Modern Plastics, Pittsfield, Massachusetts.

For further information, refer to Case Western Reserve University in Cleveland, Ohio, which maintains a fundamental research center for adhesives and coatings. http://www.cwru.edu/cse/eche/

AD HOC NETWORK. See **Bluetooth™ Wireless Technology**.

ADIABATIC ATMOSPHERE. A model atmosphere in which the pressure decreases with height according to: $p = p_0[1 - (-gz/c_{p,d}T_0)]C_{p,d}R_d$ where p_0 and T_0 are the pressure and temperature (°K) at sea level or other datum; z is the geometric height; R_d is the gas constant for dry gas; $c_{p,d}$ is the specific heat for dry gas at constant pressure; and g is the acceleration of gravity. Also called *dry-adiabatic atmosphere*, *convective atmosphere*, and *homogeneous atmosphere*.

ADIABATIC PROCESS. Any thermodynamic process, reversible or irreversible, which takes place in a system without the exchange of heat with the surroundings. When the process is also reversible, it is called *isentropic*, because then the entropy of the system remains constant at every step of the process. (In older usage, isentropic processes were called simply adiabatic, or quasistatic adiabatic; the distinction between adiabatic and isentropic processes was not always sharply drawn.)

When a closed system undergoes an adiabatic process without performing work (*unresisted expansion*), its internal energy remains constant whenever the system is allowed to reach thermal equilibrium. Such a process is necessarily irreversible. At each successive state of equilibrium, the entropy of the system S_i, has a higher value than the initial entropy, S_0. Example: When a gas at pressure p_0, temperature T_0, occupying a volume V_0 (see Fig. 1) is allowed to expand progressively into volumes $V_1 = V_0 + \Delta V$, etc., by withdrawing slides 1, 2, etc., one after another, it undergoes such a process if it is enclosed in an adiabatic container. After each withdrawal of a slide, the irreversibility of the process causes the system to depart from equilibrium; equilibrium sets in after a sufficiently long waiting period. At each successive state of equilibrium $U_1 = U_2 = \cdots = U_0$, but $S_0 < S_1 < S_2$, etc.

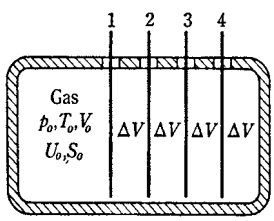

Fig. 1. Successive adiabatic expansions of gas by withdrawing slides.

When an open system in steady flow undergoes an adiabatic process without performing external work, the enthalpy of the system regains its initial value at each equilibrium state, and the entropy increases as before. Example: Successive, *slow* expansions through porous plugs $P_1, P_2 \cdots$ (Fig. 2), when we have

$$H_1 = H_2 = \cdots = H_0$$

but

$$S_0 < S_1 < S_2, \text{ etc.}$$

This process is also necessarily irreversible.

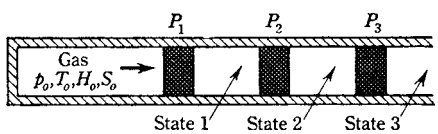

Fig. 2. Successive, slow adiabatic expansions of gas through porous plugs.

A closed system cannot perform an isentropic process without performing work. Example (Fig. 3): A quantity of gas enclosed by an ideal, frictionless, adiabatic piston in an adiabatic cylinder is maintained at a pressure p by a suitable ideal mechanism, so that $Gl = pA$ (A being the area of piston). When the weight G is increased (or decreased) by an infinitesimal amount dG, the gas will undergo an isentropic compression (or expansion). In this case,

$$S = \text{constant}, \quad dS = 0$$

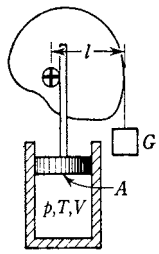

Fig. 3. Isentropic compression (or expansion) in cylinder.

at any stage of the process, but

$$U \neq \text{constant}, \quad H \neq \text{constant}$$

During an isentropic process of a closed system between state 1 and 2, the change in internal energy equals *minus* the work done between the two states, or

$$U_2 - U_1 = -W_{12}$$

work is done "at the expense" of the internal energy.

ADIABATIC TEMPERATURE CHANGES. See **Meteorology**.

ADIABATIC TEMPERATURE GRADIENT. See **Meteorology**.

ADIABATIC WALL. A perfect heat insulator. Since in a rigorous development of the principles of thermodynamics it is necessary to introduce the concept of an adiabatic wall before the concept of heat, it is convenient to adopt the following alternative definition. If two closed systems are place in contact through an adiabatic wall, their states can be varied independently of one another. Any state of one system can coexist with any state of the other system through such a wall; the systems are not coupled in any way. See **Diathermal Wall**. The number of independent properties of the combined system is equal to the sum of the number of independent properties of the component systems.

A-DISPLAY. In radar, a display in which targets appear as vertical deflections from a line representing a time base. Target distance is indicated by the horizontal position of the deflection from one end of the time base. The amplitude of the vertical deflection is a function of the received signal intensity. The A-display was the first type of radar display in common use. It may be produced by amplitude modulating the horizontal sweep of an oscilloscope with the received signal. An oscilloscope displaying this is called an *A-scope* or *A-scan*. On an A-scope the difference between the coherent echoes produced by aircraft or ships and the rapidly fluctuating incoherent echoes from precipitation is readily apparent.

ADJUSTABLE CISTERN BAROMETER. See **Cistern Barometer**.

ADOBE. An extremely fine-grained, wind-blown clay, particularly characteristic of the arid and semi-arid southwestern United States, Mexico, and South America. Used by the southwestern Indians and Mexicans for huts and buildings from prehistoric times.

ADOLESCENCE (Physiology). The period of youth extend from the beginning of puberty to adulthood. For human beings, this period usually ranges between 12 and 20 years. Physical developments in adolescence of the American male are shown in Fig. 1.

Growth during the first 10 years of life proceeds at a fairly uniform rate. The child's desires usually keep pace with his ability to meet his needs.

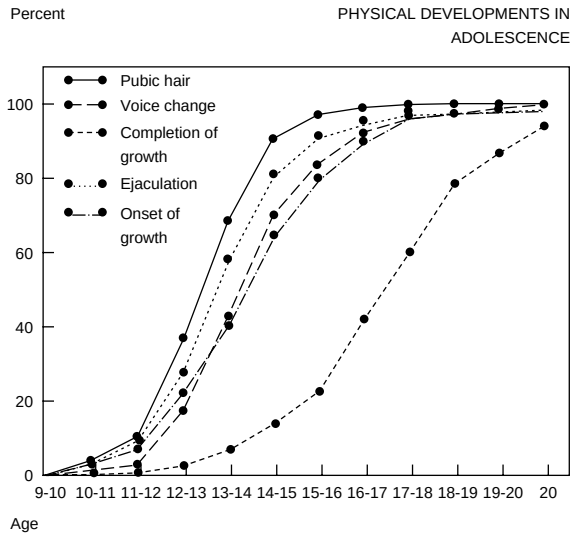

Fig. 1. This chart portrays the percentage of American males undergoing the indicated changes in physical development at various ages during adolescence.

However, during the adolescent or teenage period, there is disharmony between physiological development, growth, and emotional maturation. The teenager becomes a blend of maturity and immaturity in body, mind, and emotion.

Puberty, which refers to the sexual maturation of the individual, is only part of adolescence. Puberty and adolescence begin in the girl at 11 to 15 years of age. Boys lag about a year behind. The average age for puberty in girls in the United States is around 13.5 years and, in boys, 14.5 years. Adolescence in most American youth terminates at about 19 years of age.

The first half of adolescence is characterized by physical growth and change; the latter half brings more intellectual and emotional changes.

Adolescent growth varies widely between individuals. Failure to realize this may cause unnecessary anxiety to both parents and child. Growth rate is influenced by the state of health and nutrition. Not only is there variability in the growth of different individuals, but growth within the single individual is not harmonious. Certain parts of the body grow, while other parts lag behind. The child may grow tall without putting on weight, or he may show more sexual maturity than maturity of the digestive organs. This organ imbalance leads to organ instability. Thus, laziness and awkwardness may result. In the average boy, the period of greatest height increase is from about 12 to 14.5 years, although they continue to grow until about the age of 18. They gain most of their weight between the ages of 13 and 16. Girls grow tallest from about 10.5 to 14 years; maximum weight development is from about ages 11.5 to 14.5. As much as 6 inches (15 centimeters) in height and 25 pounds (11.3 kilograms) in weight may be gained within a single year.

Puberty in the boy is marked by growth of the sexual organs and the beginning of their function. Secondary sexual changes occur. His voice deepens; his shoulders broaden; his muscles harden; his legs lengthen; his hands and feet grow disproportionately large.

Arrival of the first menstrual period in a girl may be shocking and frightening if she is improperly prepared for the event. Menstrual irregularity and pain are common the first year or so, and are usually without significance. The broadening of hips, development of breasts, and appearance of pubic hair usually parallel the beginning of menstruation, but are subject to wide variation. Both sexes are preoccupied with their bodies and unable to take their growth for granted.

Obesity is often a problem in this period and may be a factor in delayed puberty. Whether the condition is the result of poor eating habits, of emotional instability, or of endocrine dysfunction, it merits careful investigation.

Physical maturity is reached when the body has its final height and has assumed adult proportions. The secondary sexual characteristics are fully developed, and the sexual functions have been established.

ADRENAL DISEASE. The adrenal gland comprises the adrenal medulla, which secretes noradrenaline (norepinephrine) and adrenaline (epinephrine), and the adrenal cortex, which is responsible for glucocorticoid, mineralocorticoid and androgen production. Disorders of the adrenal gland result in either excessive or deficient production of these hormones.

Introduction

The adrenal cortex is made up of three layers. The zona glomerulosa is the outermost layer and is where aldosterone is synthesized. It is predominantly under the control of the renin–angiotensin system. The middle layer, the zona fasciculata, is responsible for cortisol production and is regulated by adrenocorticotrophic hormone (ACTH) produced by the pituitary gland. Adrenal androgens are also produced in the zona fasciculata as well as in the innermost layer, the zona reticularis. The medulla is in the centre of the adrenal gland and is responsible for catecholamine (adrenaline) secretion.

Disorders of the adrenal gland may result in hormonal deficiency, of which cortisol and aldosterone deficiency are clinically significant. Conversely, the adrenal gland may produce hormones to excess, resulting in distinct clinical syndromes. This article discusses the various disorders produced by adrenal gland pathology. See **ACTH**.

Normal Physiology of the Adrenal Gland

The normal adrenal gland secretes cortisol in response to ACTH secretion by the pituitary gland, which in turn is controlled by corticotrophin-releasing hormone (CRH) from the hypothalamus. Cortisol feedback then inhibits the release of both CRH and ACTH (Fig. 1). All the secretions are subject to diurnal variation, increasing at 03.00–04.00 hours and peaking at around 08.00 hours. Levels then decline to become undetectable between 11.00 and 01.00 hours if subjects are asleep. This rhythm is interrupted by pulsatile bursts of increased ACTH and cortisol secretion, precipitated by physical and psychological stress, including food intake. See also **Pituitary Gland.**

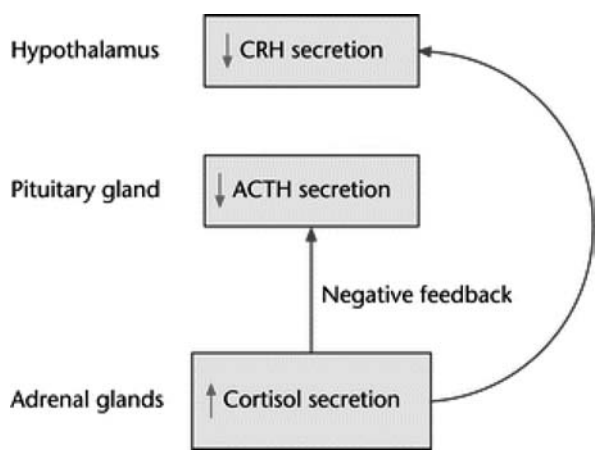

Fig. 1. Regulation of cortisol synthesis. ACTH, adrenocorticotrophic hormone; CRH, corticotrophin-releasing hormone.

Adosterone is primarily under the control of the renin–angiotensin system, with secretion being stimulated by intravascular volume contraction. ACTH and hyperkalaemia may also stimulate aldosterone production (Fig. 2).

Actions of Glucocorticoids

Cortisol is essential for life, particularly during stress, such as infection or trauma.

Actions of Mineralocorticoids

Aldosterone is essential for maintaining intravascular volume, electrolyte balance and arterial blood pressure by promoting renal tubular reabsorption of sodium and excretion of potassium.

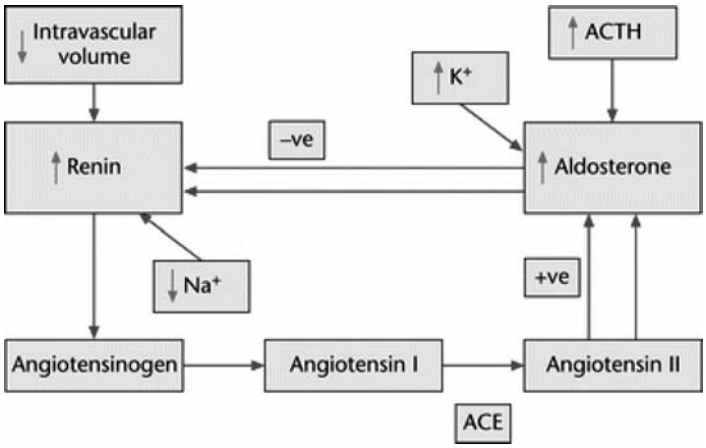

Fig. 2. Regulation of aldosterone synthesis. ACE, angiotensin-converting enzyme; ACTH, adrenocorticotrophic hormone.

Actions of Catecholamines

Noradrenaline (norepinephrine) and adrenaline (epinephrine) stimulate the sympathetic nervous system, thereby increasing blood pressure, myocardial contractility and heart rate. They also stimulate hepatic glucose production. Noradrenaline causes generalized vasoconstriction but adrenaline induces vasodilatation in skeletal muscle vascular beds. Catecholamine secretion is normally triggered by physical or psychological stress. See also **Adrenaline and Noradrenaline**.

Addison Disease

Addison disease, or primary adrenal insufficiency, is caused by the destruction of the adrenal cortex. It occurs with an estimated prevalence of 50 per million population [Oelkers, 1996]. The most common cause of Addison disease in the Western hemisphere is autoimmune adrenal gland destruction, which is more common in females and has a peak incidence in the fourth decade. Tuberculosis is the second commonest cause of adrenal insufficiency. Causes of primary adrenal insufficiency are:

1. Autoimmune adrenalitis
2. Tuberculosis
3. Other infections
    1. viral (e.g., human immunodeficiency virus, cytomegalovirus)
    2. fungal (e.g., histoplasmosis, cryptococcosis)
    3. Bacterial (e.g., meningococcal septicemia)
4. metastases (e.g., breast, lung, kidney)
5. Adrenoleucodystrophy
6. Congenital adrenal hyperplasia
7. Infiltrative disorders (e.g., sarcoidosis, amyloidosis)
8. Drugs (e.g., ketoconazole, fluconazole, aminoglutethimide)
9. Adrenal hemorrhage (e.g., anticoagulants, sepsis)

See also **Tuberculosis**.

Pathophysiology

There is a failure in adrenal gland function, resulting in cortisol and aldosterone deficiency (Fig. 3). This usually occurs gradually over a number of years. However, acute adrenal insufficiency may develop following adrenal hemorrhage, or with septicemia (e.g., meningococcal).

Cortisol deficiency results in the loss of negative feedback on the pituitary production of ACTH, which is thus markedly increased. ACTH is responsible for skin pigmentation in humans, so hyperpigmentation is present in Addison disease.

Renin is oversecreted by the kidneys in response to aldosterone deficiency.

Major Clinical Features and Complications

In general, more than 90% of adrenocortical destruction occurs before symptoms develop [Tyrrell, ref.]. The presence of a physical stress, for example pneumonia or a car accident, may precipitate the onset of symptoms at an earlier stage.

In autoimmune adrenalitis, the symptoms and signs are usually of insidious onset and are often nonspecific: fatigue; weight loss; dizziness; joint

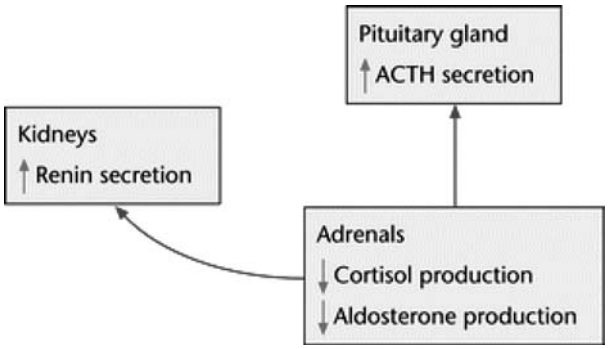

Fig. 3. Pathophysiology of primary adrenal insufficiency. ACTH, adrenocorticotrophic hormone.

and muscle pains; gastrointestinal symptoms (e.g., anorexia, nausea, diarrhoea, abdominal cramps); salt craving; hyperpigmentation; and postural hypotension.

Hyperpigmentation is a characteristic feature of Addison disease and distinguishes it from adrenal insufficiency secondary to pituitary or hypothalamic disease. It usually occurs on the exposed parts of the body, pressure points, skin creases and scars, as well as in the buccal mucosa and breast areole. Postmenopausal women may lose axillary and pubic hair because of loss of adrenal androgen secretion.

Other symptoms depend on the aetiology of the illness. About half of patients with autoimmune Addison disease develop other autoimmune disorders such as hypothyroidism, hypoparathyroidism or premature ovarian failure. In acute adrenal insufficiency precipitated by trauma or infection, for example, hypotension, and hypoglycemia, if left untreated, death may occur.

Investigations

Relevant investigations are outlined below; see also Table 1.

TABLE 1. EFFECT OF ADDISON DISEASE ON GENERAL INVESTIGATIONS

Investigation	Finding in Addison disease
Full blood count	Mild normocytic anaemia, eosinophilia, lymphocytosis
Urea and electrolytes	Hyponatremia, raised urea level, mild hyperkalaemia and acidosis
Blood glucose	May be low
Serum calcium	Mild hypocalcaemia (occasionally)
Chest radiography	Small heart

09.00 Hours Cortisol. Serum cortisol level of less than 70 mmol L^{-1} is diagnostic of adrenal insufficiency.

Serum cortisol level of greater than 580 $mmol^{-1}$ indicates normal adrenal function.

Serum cortisol levels between those values require further evaluation. Additionally, Addison disease should be excluded in someone who is acutely ill with a cortisol concentration of less than 500 mmol L^{-1}.

Synacthen Test (09.00–10.00 Hours). ACTH is given and serum cortisol level is measured basally, 30 and 60 min after injection. Serum cortisol should rise above 580 mmol LL^{-1} In patients with adrenal insufficiency, peak cortisol levels do not reach this cut-off and are often undetectable by the time the patient is symptomatic.

ACTH. Plasma ACTH levels are markedly raised in primary adrenal insufficiency.

Renin and Aldosterone. Plasma renin concentrations are increased and plasma aldosterone levels are low.

Adrenal Autoantibodies. Antibodies against the adrenal cortex are found in 60–90% of patients with autoimmune adrenal disease.

Adrenal Gland Imaging. In autoimmune disease, computed tomography (CT) or magnetic resonance imaging (MRI) will show atrophic glands. The adrenal glands are usually enlarged in patients with metastases or infection, and in those with tuberculosis calcification may be seen.

Summary

Addison disease is a rare illness caused by destruction of the adrenal cortex. The most common cause is autoimmune disease. Undiagnosed, it may cause death. It is diagnosed by demonstrating cortisol deficiency associated with markedly raised ACTH levels, and aldosterone deficiency is also usually present. Treatment is by means of glucocorticoid and mineralocorticoid replacement therapy. See also **Addison's Disease**.

Adrenal Causes of Cushing Syndrome

Cushing syndrome is an illness resulting from prolonged exposure of tissues to excessive endogenous secretion of cortisol. Untreated, it is associated with significant morbidity and mortality [Meier and Biller, ref.]. The source of steroid excess may be classified into ACTH-dependent (pituitary and ectopic ACTH secretion) and ACTH-independent (primary adrenal) disease. This section discusses adrenal causes of Cushing syndrome as ACTH-dependent causes are considered elsewhere (see **Pituitary Gland**).

Frequency and Clinical Importance

Cushing syndrome is estimated to affect 10–40 per million population, and adrenal disease accounts for 20% of cases. Benign adenomas and carcinomas comprise the majority of these (Table 2). It is more prevalent in women and has a peak incidence in the fourth and fifth decades of life.

TABLE 2. CAUSES AND RELATIVE FREQUENCIES OF ADRENAL CUSHING SYNDROME IN ADULTS

Cause	Frequency (%)
Adrenal adenoma	10
Adrenal carcinoma	8
Bilateral micronodular cradrenal hyperplasia	1
Bilateral macronodular hyperplasia	1

Major Clinical Features and Complications

The clinical features associated with Cushing syndrome are summarized in Table 3. The severity of symptoms and signs and the rate of progression depend on the cause of Cushing syndrome. Adrenal carcinoma is often rapidly progressive with evidence of virilization, whereas benign causes usually develop insidiously over a number of years. It is often helpful to compare the patient's current appearance with an old photograph to show disease development.

TABLE 3. CLINICAL FEATURES AND COMPLICATIONS CASHING SYNDROME

Feature	Finding in Cushing syndrome
Fat metabolism	Central obesity, buffalo hump, supraclavicular fat pad
	Atherosclerosis, hyperlipidemia
Protein catabolism	Proximal myopathy and muscle wasting
	Thin skin, easy bruising, wide purple striae
	Poor wound healing
Carbohydrate metabolism	Diabetes mellitus
Electrolyte balance	Hypertension, polyuria, lower limb oedema
Androgen excess	Hirsutism, acne, amenorrhea in females
Effect on bone	Osteoporosis
	Growth failure in children
Neurological	Psychiatric and personality disorders
	Hypogonadotrophic hypogonadism

Many of the clinical features described are not specific for Cushing syndrome. However, the presence of truncal obesity, round facies, thin skin with striae and proximal myopathy are specific signs that require further investigation.

Investigation

Figure 4 summarizes the investigation of adrenal Cushing syndrome.

Diagnosis of Cushing Syndrome

24-h Urinary Free Cortisol (UFC). This is a good screening test for excessive glucocorticoid production provided the urine collection is complete; 95% sensitivity may be achieved by multiple testing.

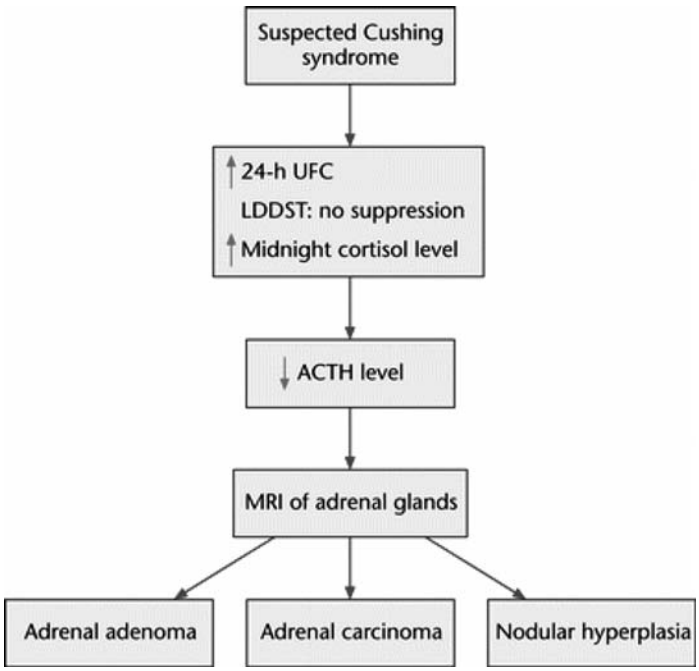

Fig. 4. Diagnosis of adrenal Cushing syndrome. ACTH, adrenocorticotrophic hormone; LDDST, low-dose dexamethasone suppression test; MRI, magnetic resonance imaging; UFC, urinary free cortisol.

Midnight Serum Cortisol. In Cushing syndrome there is loss of the diurnal variation in cortisol secretion. A detectable midnight cortisol level in a sample taken during sleep is highly sensitive for Cushing syndrome.

Low-dose Dexamethasone Suppression Test. 0.5 mg dexamethasone is given every 6 h for 48 h, starting at 09.00 hours, and serum cortisol concentration is measured basally and then following test completion. Normally, cortisol suppresses to less than 50 mmol L^{-1}, but in Cushing syndrome there is failure of suppression of cortisol in response to dexamethasone.

False positives occur in patients who are taking drugs that may increase dexamethasone metabolism, or oestrogen therapy which increases the level of total cortisol by increasing the level of cortisol-binding globulin (CBG).

False-positive results on the above tests may be found in patients with other conditions associated with a mildly raised 24-h UFC level: simple obesity depression and other psychiatric disorders alcohol abuse diabetes mellitus and glucocorticoid resistance.

Diagnosis of Aetiology of Cushing Syndrome

ACTH. This is the best way to discriminate between ACTH-dependent and ACTH-independent disease. ACTH levels at 09.00 hours are undetectable in patients with Cushing syndrome secondary to an adrenal pathology, although they may be detectable in low concentrations in nodular hyperplasia.

Radiological Imaging. Adrenal MRI or CT should be performed if ACTH levels are low. Adrenal adenomas are between 2 and 6 centimeters (0.8 and 2.4 inches) in size, whereas carcinomas are usually greater than 6 centimeters (2.4 inches) and are locally invasive [Harper and Atkinson, ref.]. The contralateral gland is often atrophic, particularly in the presence of a long-standing adenoma. In adrenocortical nodular hyperplasia, both glands are enlarged with multiple nodules.

Serum Potassium. Serum potassium levels may be low in patients with adrenal carcinoma owing to the mineralocorticoid effect of the high cortisol levels.

High-dose Dexamethasone Suppression Test. There is failure of 09.00 hours cortisol to suppress to less than 50% of basal value following the administration of 2 mg dexamethasone 6 hourly for 48 h in patients with adrenal Cushing syndrome, distinguishing it from pituitary disease.

CRH Test. In adrenal Cushing syndrome, ACTH and cortisol levels fail to rise after CRH stimulation.

Management

Adrenal Adenoma. Unilateral adrenalectomy is curative. Patients with severe disease may require treatment for a few weeks before operation with an adrenal enzyme inhibitor such as metyrapone or ketoconazole to prevent poor wound healing.

Patients are glucocorticoid deficient after operation as a result of suppression of ACTH secretion. Steroid replacement is therefore required. It may take several years for the hypothalamopituitary axis, and therefore the contralateral gland, to recover sufficiently to discontinue the glucocorticoids.

Adrenal Carcinoma. Adrenalectomy should be performed, although it is rarely curative. Detectable postoperative cortisol levels indicate persistent or metastatic disease. Mitotane, metyrapone and ketoconazole may all be used as single agents or in combination to control hypercortisolism after operation, but do not affect survival. The 5-yr survival rate is 20–30%.

Bilateral Nodular Hyperplasia. Bilateral adrenalectomy followed by glucocorticoid and mineralocorticoid replacement therapy is curative.

Summary

Cushing syndrome is caused by excessive glucocorticoid secretion, and adrenal disease accounts for one-fifth of patients. It is associated with significant morbidity and, if untreated, mortality, so early diagnosis is essential. Following the demonstration of hypercortisolism, ACTH levels should be determined. If ACTH is undetectable, an adrenal pathology is likely and may be confirmed by adrenal MRI. Adrenalectomy is curative unless an adrenocortical carcinoma is present. Drugs such as metyrapone may be used to control hypercortisolism before operation, and after surgery in the case of malignant disease. Prognosis after treatment is excellent in patients with benign disease, but poor in the presence of malignancy.

Primary Hyperaldosteronism

Primary hyperaldosteronism accounts for at least 2% of hypertensive patients [Ganguly, ref.] and is characterized by hypertension in association with hypokalemia and suppressed plasma renin activity. The most common cause is a benign adrenal adenoma, or Conn syndrome. Hyperaldosteronism may also be a result of bilateral or unilateral hyperplasia of the adrenal glands. Glucocorticoid-suppressible aldosteronism is an inherited form of primary hyperaldosteronism. Finally, adrenocortical carcinoma and ectopic aldosterone-producing tumors are rare causes of primary hyperaldosteronism (Table 4). See also **Hypertension**.

TABLE 4. CAUSES OF PRIMARY HYPERALDOSTERONISM AND THEIR RELATIVE FREQUENCY

Cause	Frequency (%)
Conn syndrome (adrenal adenoma)	66
Adrenocortical hyperplasia	
Bilateral	30
Unilateral	1
Glucocorticoid-remediable aldosteronism	1
Other (adrenocortical carcinoma, ectopic aldosterone production)	2

Pathophysiology

In primary hyperaldosteronism, aldosterone secretion is independent of renin and is not suppressed by a salt load, changes in intravascular volume or posture. Additionally, its secretion is more sensitive to ACTH and may be reduced by the administration of exogenous glucocorticoids. In glucocorticoid-remediable aldosteronism, secretion is under the total control of ACTH and thus plasma levels of aldosterone mimic the diurnal rhythm of ACTH secretion. Plasma renin levels are suppressed in all cases of primary hyperaldosteronism through negative feedback on the renal juxtaglomerular apparatus.

Major Clinical Features and Complications

Primary hyperaldosteronism is most commonly diagnosed between the third and sixth decades, although glucocorticoid-remediable aldosteronism often presents with hypertension in childhood. Conn adenoma is more common in women, whereas adrenal hyperplasia has a male dominance.

Moderately severe hypertension is the main feature, and is often resistant to conventional therapy. Symptomatic hypokalemia is uncommon, and most patients are asymptomatic. The occasional patient may present with tetany, cramps, muscle weakness and nocturia from severe hypokalemia (hypokalaemia).

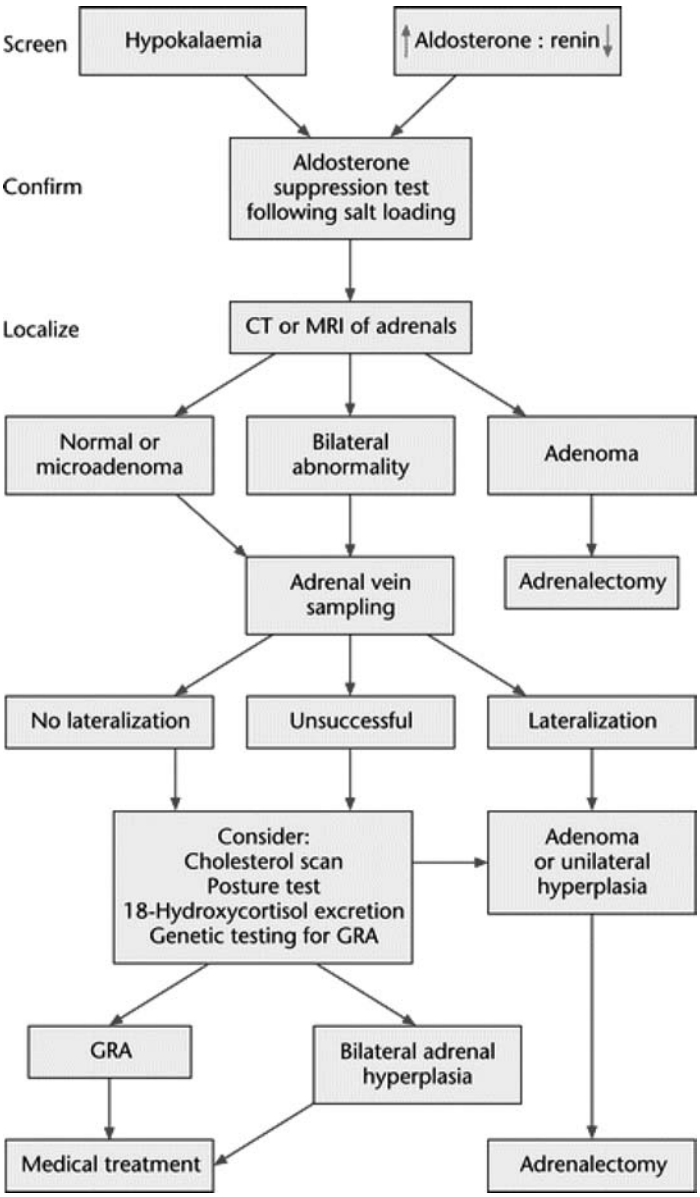

Fig. 5. Investigation of primary hyperaldosteronism. CT, computed tomography; GRA, glucocorticoid-remediable aldosteronism; MRI, magnetic resonance imaging.

Investigations. Stages in the investigation of primary hyperaldosteronism are shown in Figure 5.

Many of the clinical features described are not specific for Cushing syndrome. However, the presence of truncal obesity, round facies, thin skin with striae and proximal myopathy are specific signs that require further investigation.

Screening. All patients with (1) hypertension resistant to conventional treatment and (2) hypertension and concomitant hypokalemia, including those on diuretics, should be screened for primary hyperaldosteronism.

Serum Potassium. Hypokalemia is highly suggestive of primary hyperaldosteronism in a hypertensive subject. However, approximately 30% of patients with hyperaldosteronism and most patients with glucocorticoid-remediable aldosteronism are normokalemic [Vallotton, ref.]. Metabolic alkalosis is common and serum sodium concentration is often in the high normal range.

24-h Urine Potassium Excretion. Urinary potassium excretion in excess of 30 mmol per 24 h following the discontinuation of diuretics and in the presence of hypokalaemia is suggestive of hyperaldosteronism.

Plasma Aldosterone : Renin Ratio. Plasma renin is suppressed in patients with primary hyperaldosteronism, but may also be suppressed in one-third of patients with essential hypertension. Additionally, plasma renin levels are influenced by sodium ingestion and some antihypertensive medications.

Calculation of the aldosterone : renin ratio improves the diagnostic accuracy of plasma renin measurements as it is less affected by variations in both renin and aldosterone secretion. A high ratio (greater than 30) is very suggestive of primary hyperaldosteronism. Hypokalaemia should be corrected before testing as hypokalemia may suppress aldosterone secretion. Additionally, β-blockers suppress renin production and should be discontinued before investigation. Optimal antihypertensive therapy during investigation of possible primary hyperaldosteronism is with an α antagonist or calcium channel blocker.

Confirmatory Tests

Aldosterone Suppression Testing Following Salt Loading. Normally, salt loading will suppress aldosterone production. However, in primary hyperaldosteronism it will have little effect on its secretion. Patients should have stopped antihypertensive medication that is likely to affect aldosterone production at least 2 weeks, and spironolactone at least 6 weeks, before testing. Additionally, as salt loading can exacerbate hypokalemia, this should be corrected beforehand. Oral salt loading for 3 days with a high sodium diet and, if necessary, sodium supplementation (total 2–3 g sodium per day) is the safest option. Raised plasma aldosterone level following salt loading is diagnostic of primary hyperaldosteronism.

Differential Diagnosis

Adrenal Computed Tomography and Magnetic Resonance Imaging. Imaging should be performed only after biochemical confirmation of aldosteronism. Radiological imaging can detect most adenomas. If these are greater than 1 centimeter (0.4 in) in diameter and the contralateral gland is normal, the diagnosis of a Conn adenoma is clear. However, if the adrenal glands appear normal, or if there are bilateral adrenal abnormalities or the nodule is less than 1 centimeter (0.4 in) in diameter, further tests are required to diagnose the cause of aldosterone excess accurately. Adrenal carcinoma should be suspected if a tumor larger than 3 centimeter (1.2 in) is found.

Adrenal Venous Sampling. This is the "gold standard" test for diagnosing the source of hyperaldosteronism. Aldosterone is measured in blood taken from both adrenal veins. A concentration gradient between the adrenal veins indicates a surgically treatable cause (unilateral hyperplasia or adenoma). However, cannulating the adrenal veins, particularly the right adrenal vein, is fraught with difficulty. Cortisol should be measured concomitantly to confirm successful adrenal vein sampling before interpreting results indicative of lateralization.

Radiolabelled Cholesterol Scanning. This may be useful if the results of radiological imaging are equivocal and adrenal vein sampling unsuccessful. There is a unilateral increase in tracer uptake in the presence of an adenoma, but no uptake in hyperplasia. Dexamethasone suppression of cortisol production should be performed before the procedure to prevent false-positive results. However, this test has an accuracy of approximately 70%.

Posture Test. This relies on the fact that aldosterone production from an adenoma is independent of posture, whereas in adrenal hyperplasia there is a rise in aldosterone production after maintaining an upright posture. Plasma aldosterone is therefore measured on waking and then again 2–4 h after getting up. Failure of plasma aldosterone concentration to increase is suggestive of an adenoma. However, this has an accuracy of 80% as some adenomas do respond to posture and patients with hyperplasia may fail to do so.

24-h Urine 18-hydroxycortisol Excretion. Levels of this precursor of aldosterone are markedly increased in glucocorticoid-remediable aldosteronism. However, concentrations are also raised in patients with Conn adenoma and may be high in those with adrenal hyperplasia.

Genetic Testing. Glucocorticoid-remediable aldosteronism is the result of a characteristic gene duplication and there is now a definitive genetic test to detect this with 100% accuracy.

Management

Conn Adenoma. Adrenalectomy is the treatment of choice. Pretreatment with spironolactone for at least 4 weeks before surgery can predict surgical response and minimize postoperative complications from hypoaldosteronism. Hypertension is often cured, and if it persists is more amenable to medical treatment.

Unilateral Hyperplasia. This is also surgically treatable, with postoperative improvement in blood pressure.

Bilateral Hyperplasia. Bilateral disease is managed medically with the aldosterone antagonist spironolactone. Side effects are common when higher doses of spironolactone are used, particularly gynecomastia and impotence in men, menstrual irregularities in women and gastrointestinal effects.

Glucocorticoid-remediable Aldosteronism. Hypertension responds to dexamethasone (0.5–2 mg per day). However, this is not without its side effects, so spironolactone treatment, which is equally effective, is preferred.

Summary

Primary hyperaldosteronism is the most common cause of secondary hypertension. Patients with hypertension and hypokalaemia, and those with hypertension resistant to treatment, should be screened. A low renin concentration in combination with a raised aldosterone level that fails to suppress following salt loading confirms the diagnosis. The most common cause is an adrenal adenoma, which is best localized by CT or MRI. Treatment is by adrenalectomy. Other forms of hyperaldosteronism usually represent bilateral adrenal disease and are best treated with spironolactone.

Pheochromocytoma (Phaeochromocytoma)

Pheochromocytomas are catecholamine-producing tumors arising from the chromaffin cells of the adrenal medulla. Chromaffin cells are also found around the sympathetic ganglia. Tumors of these extra-adrenal cells are known as paragangliomas.

Pheochromocytoma accounts for 0.1% of all cases of hypertension. It has a peak incidence in the fourth decade and affects both sexes equally. Some 10% of tumors develop in childhood, and 10% of tumors are familial (Table 5). Pheochromocytomas are bilateral in 10% of cases, especially when part of a familial syndrome, when the frequency of bilateral tumors approaches 50%. Ten percent of tumors are extra-adrenal. Paragangliomas may occur anywhere along the sympathetic chain, but 80% are intra-abdominal. Some 10% of pheochromocytomas are malignant, particularly those developing outside the adrenal medulla. See also **Cancer and Oncology** and **Hypertension**.

Pathology

Macroscopically, pheochromocytomas are encapsulated and are variable in size. The cut surface is brown in color with areas of hemorrhage and necrosis. The normal adrenal tissue is usually compressed and displaced. Microscopically, the tumor cells are larger than normal chromaffin cells, and are more pleomorphic. Malignancy cannot be diagnosed from histological appearance alone, but requires evidence of local invasion or distant metastasis. Pheochromocytomas usually secrete noradrenaline, and some also secrete adrenaline. Dopamine-secreting tumors are rare. Other vasoactive peptides may also be secreted but rarely in sufficient amounts to produce symptoms.

Clinical Features

Symptoms are related to excessive sympathetic stimulation: Hypertension; headache; sweating; palpitations; pallor; epigastric and chest pain; nausea; anxiety; tremor; dyspnoea; postural hypotension; weight loss; and constipation.

Hypertension is the hallmark of the diagnosis, present in over 90% of patients, and is often resistant to conventional treatment. It may be intermittent but is often persistent with paroxysmal exacerbations.

The differential diagnosis is extensive, including other causes of hypertension and paroxysmal attacks: Other causes of hypertension; anxiety; thyrotoxicosis; menopausal symptoms; medullary thyroid carcinoma; hypoglycemia; carcinoid tumor; migraine; cerebrovascular accident; abdominal catastrophe; and cardiovascular disease.

Hypertensive crises may be precipitated by a general anesthetic. Paroxysmal attacks of palpitations associated with sweating, feeling of impending doom, breathlessness and headaches develop in 50% of patients. These attacks may last for minutes to hours and usually occur spontaneously. However, they may be precipitated by exercise, straining, abdominal palpation, surgery or certain drugs (anesthetic agents, β-blockers, antihistamines, opiates, glucagon, tricyclic antidepressants, phenothiazines, metoclopramide, adrenocorticotrophin). Family history is important because pheochromocytomas may be inherited in an autosomal dominant fashion, either in isolation or as part of a syndrome (see Table 5).

TABLE 5. FAMILIAL PHEOCHROMOCYTOMA

Cause	Features
Isolated pheochromocytoma	Autosomal dominant inheritance
Multiple endocrine neoplasia type II	Medullary cell carcinoma of the thyroid gland, hyperparathyroidism, pheochromocytoma; accounts for 4% of all pheochromocytomas
von Hippel–Lindau syndrome	Renal cell carcinoma, cerebellar hemangioblastoma, retinal angioma, renal and pancreatic cysts; pheochromocytoma in 25% of cases
Neurofibromatosis	Café au lait spots, skin fibromas, meningiomas, acoustic neuroma and pheochromocytoma

Pheochromocytoma is potentially fatal; complications include:

- Hypertensive complications (cardiac, renal, retinal)
- Ventricular and supraventricular arrhythmias
- Myocardial infarction
- Left ventricular failure
- Cardiomyopathy (dilated or hypertrophic)
- Acute abdomen (ischemic bowel, infarction of or hemorrhage into pheochromocytoma)
- Cerebrovascular accident

A high index of suspicion is therefore required and the threshold for screening should be low. The following patient groups should be screened:

1. A hypertensive crisis during induction of anesthesia
2. Hypertension with paroxysmal symptoms
3. Hypertension that is resistant to conventional treatment
4. A positive family history for pheochromocytoma, multiple endocrine neoplasia II (MEN II), von Hippel–Lindau syndrome (VHL) or neurofibromatosis.

Investigations

24-h Urine Collection for Catecholamines. The diagnosis is confirmed by demonstrating catecholamine hypersecretion. Collections should be in acid containers and be tested for free catecholamines, which have a sensitivity and specificity of 95%. Urinary metanephrines are also highly sensitive but may be affected by stress, smoking and medication. At least a 2-fold increase above the upper limit of normal is usually seen in pheochromocytoma. Determination of vanillylmandelic acid (VMA) levels is less accurate and should not be measured. Tricyclic antidepressants and labetalol should be stopped 4–7 days before diagnostic evaluation, but other medication may be continued. There are no dietary restrictions during the investigation period.

Abdominal Magnetic Resonance Imaging. Some 90% of pheochromocytomas are found in the adrenal gland and 98% are found in the abdomen. MRI is highly sensitive at localizing these tumors, with a pick-up rate approaching 100%. If negative, an extra-abdominal paraganglioma should be sought by whole-body MRI.

^{123}I-MIBG (meta-iodobenzylguanidine) Scan. This may visualize lesions not seen on MRI. It is also useful for looking for multiple tumors and metastases. However, its sensitivity is only 70% [Bouloux and Fakeeh, ref.].

Plasma Catecholamines. Estimation of plasma catecholamine concentration is less accurate and is not indicated if urinary catecholamine levels are unequivocal. Plasma catecholamine levels are affected by a number of drugs and stress. However, if levels are raised during a paroxysmal attack, the diagnosis is confirmed. Conversely, if levels are normal during symptoms, the diagnosis of a pheochromocytoma as a cause of the symptoms is excluded

Selective Venous Sampling. This may be used to localize a pheochromocytoma if imaging is negative despite raised levels of urinary catecholamines. The normal noradrenaline : adrenaline ratio from the adrenal veins is 1 : 4. In pheochromocytoma this ratio is reversed as noradrenaline is the catecholamine predominantly secreted to excess in these tumors.

Differential Diagnosis. The following need to be ruled out: (a) familial syndromes (e.g., serum calcium and calcitonin estimation to exclude MEN II, fundoscopy and cerebellar MRI to exclude VHL); and (b) complications (e.g., electrocardiography, chest radiography, creatinine, urea and electrolytes).

Management

Medical

1. α blockade–phenoxybenzamine should be started as soon as the diagnosis is made.
2. β blockade–propranolol is started 72 h after phenoxybenzamine. It should not be given before α blockade as this may result in a hypertensive crisis from unopposed α-adrenergic stimulation.

Medical treatment is started in hospital as the reduction in vascular tone caused by treatment may result in significant hypotension and hemodilution. Blood pressure, pulse and hemoglobin levels should be monitored closely. A blood transfusion may be required before operation. Surgery should be postponed until at least 10 days after initiating medical treatment.

Surgical. Adrenalectomy is curative in the majority of patients. Cure is assessed by 24-h urinary catecholamine measurement, but this should be delayed until at least 2 weeks after operation. Blood pressure is normalized in more than three-quarters of patients following surgery.

Follow-up. Lifelong follow-up is required, with annual blood pressure and 24-h urinary catecholamine measurements, looking for recurrence of a benign lesion or metastasis from a malignant tumor.

Malignant pheochromocytomas require long-term α and β blockade. Metastases occur locally, in the liver, lungs and bone, and have been treated with high-dose ^{131}I-MIBG with disappointing results. Combination chemotherapy may be effective in some patients, with symptomatic improvement and tumor shrinkage. Radiotherapy may provide palliation in patients with bone metastases. The overall 5-year mortality rate of patients with malignant pheochromocytoma is 44% [Daly and Landsberg, ref.].

Summary

Pheochromocytoma is a rare but treatable cause of hypertension. It is also potentially fatal, so a high index of suspicion is warranted. Diagnosis is made by the presence of raised levels of urinary catecholamines, and the tumor is best localized by MRI of the abdomen. Surgery is usually curative but should be undertaken only after adequate α and β blockade. Patients with nonmalignant pheochromocytomas have an excellent prognosis but, as malignancy is diagnosed only in the presence of metastases or local invasion, they require lifelong follow-up.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is an inherited group of disorders characterized by a deficiency of one of the enzymes necessary for cortisol biosynthesis. More than 90% of cases are due to 21-hydroxylase deficiency. CAH is inherited in an autosomal recessive manner and is most common in people of Jewish origin.

Pathogenesis

The gene encoding for the 21-hydroxylase enzyme is located on the short arm of chromosome 6. 21-Hydroxylase deficiency results from a mutation of this gene, which results in aldosterone and cortisol deficiency. There is ACTH oversecretion because of the loss of negative feedback, and this causes adrenocortical hyperplasia and excessive accumulation of 17-hydroxyprogesterone and other steroid precursors. These are then shunted into androgen synthesis pathways, resulting in testosterone and androstenedione excess (Fig. 6).

Frequency

Complete 21-hydroxylase deficiency occurs with an estimated incidence of 1 in 10 000–15 000 births, depending on racial origin. However, partial deficiency is common (1 in 27–1000 births). Other enzyme deficiencies are rare.

Major Clinical Features

The clinical features are a result of excessive androgen production and cortisol deficiency. The clinical spectrum is wide, ranging from presentation in the neonatal period with salt wasting and virilization to nonclassical CAH presenting in adulthood (Table 6).

TABLE 6. CLINICAL FEATURES OF CONGENITAL ADRENAL HYPERPLASIA

Enzyme Deficiency	Clinical Features
Classical 21-hydroxylase	Salt wasting, ambiguous genitalia in females, precocious pubarche in males
Nonclassical 21-hydroxylase (partial deficiency)	Hirsutism, oligomenorrhoea (irregular periods) in pubertal (adolescent) girls, asymptomatic in boys
11 β-hydroxylase	Ambiguous genitalia, virilization, hypertension
β-hydroxylase	Mild virilization, salt wasting in severe cases
17-hydroxylase	Delayed puberty in females, pseudohermaphroditism in males, hypertension, hypokalemia

Diagnosis is confirmed with the investigations summarized in Table 7.

Management

The aims of treatment of CAH (see Table 8) are:

- to reduce virilization and improve growth in childhood
- to maintain normal energy levels and weight, and to avoid adrenal crises in all patients

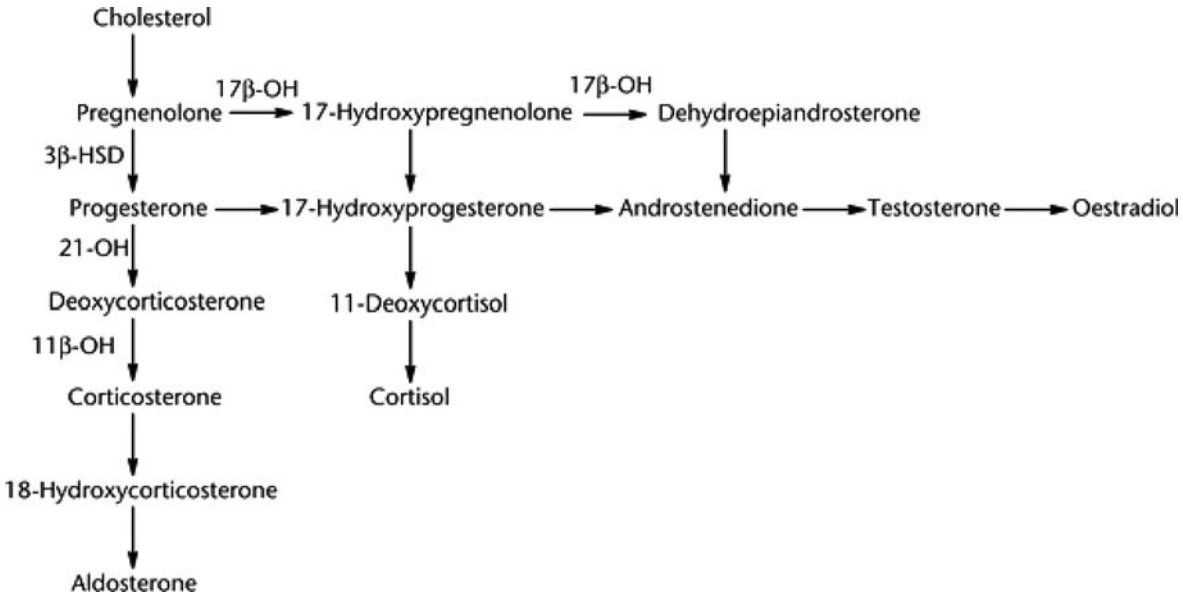

Fig. 6. Adrenal steroid biosynthesis pathway. 3 β -HSD, 3 β-hydroxysteroid dehydrogenase; 21-OH, 21-hydroxylase; 11 β-OH, 11 β-hydroxylase; 17 β-OH, 17 β-hydroxylase.

TABLE 7. INVESTIGATION OF CONGENITAL ADRENAL HYPERPLASIA[a]

Test	Result
17-Hydroxyprogesterone	Markedly increased concentration
ACTH test	To diagnose partial 21-hydroxylase deficiency in patients with equivocal 17-hydroxyprogesterone levels. Exaggerated rise of 17-hydroxyprogesterone concentration in response to ACTH stimulation indicates nonclassical CAH
Androgens	Increased testosterone and androstenedione levels
Renin	High level
ACTH	High level

[a] ACTH, adrenocorticotrophic hormone; CAH, congenital adrenal hyperplasia.

TABLE 8. TREATMENT OF CONGENITAL ADRENAL HYPERPLASIA

Treatment	Clinical Details
Glucocorticoids	Hydrocortisone is used in children as this is least likely to inhibit growth. In adulthood, longer-acting steroids such as prednisolone may be used, giving the higher dose at night, in order to suppress the morning surge of adrenocorticotrophic hormone and thus androgen secretion. Doses must be doubled during illness (see section on Addison disease)
Mineralocorticoids	Fludrocortisone is given to normalize renin levels and prevent salt wasting
Monitoring therapy	Clinically–growth in childhood and evidence of hyperandrogenism in females. Monitor 17-hydroxyprogesterone, testosterone, androstenedione and renin levels

- to minimize hyperandrogenism and to restore regular menses and fertility in females

Summary

CAH is inherited in an autosomal recessive manner. 21-Hydroxylase deficiency is responsible for approximately 95% of cases and is due to a gene mutation.

The diagnosis is made by the presence of a raised level of 17-hydroxyprogesterone at 09.00 hours, either basally or following ACTH stimulation. Patients should be maintained on glucocorticoid and fludrocortisone treatment, and therapy is monitored by determining 17-hydroxyprogesterone and renin levels. Adult height is, on average, two standard deviations below that of the normal population and fertility is reduced, particularly in salt wasters. With the development of new therapies, it is hoped that height and fertility potential will improve.

Multiple Endocrine Neoplasia

This group of disorders is characterized by endocrine tumors which usually secrete hormones to excess. MEN I and II are inherited in an autosomal dominant manner. Table 9 summarizes the clinical and genetic characteristics of the syndromes. They are rare, with an estimated prevalence of 20–200 per million live births.

Relatives of affected patients should be screened for the development of the syndrome. In families with MEN I, screening is performed by measurement of the serum levels of calcium, prolactin and gut hormones. In families with MEN IIa and b, genetic screening is now possible, looking for mutations of the *RET* proto-oncogene. See also **Oncogenes**.

ADRENAL GLANDS. Part of the endocrine system, the adrenal glands are two small bodies located at the upper end of each kidney. The right adrenal gland is somewhat triangular in shape; the left gland is more semilunar. These glands range in size, but on the average weigh from 5 to 9 grams (0.2 to 0.3 ounce). Surrounding each gland is a thin capsule. There are two parts — the *cortex* (external tissue) and the *medulla* (chromophil tissue). These parts differ both in origin and function. In proportion to total

TABLE 9. GENETICS AND CLINICAL FEATURES OF MULTIPLE ENDOCRINE NEOPLASIA (MEN)

Syndrome	Genetics	Clinical Features
MEN I	Mutation of gene located on chromosome 11	Hyperparathyroidism in 95% (usually due to multiple gland hyperplasia rather than a single adenoma) Pancreatic islet cell tumors in 40% (e.g., insulinoma, gastrinoma) Pituitary tumors in 30% (e.g., prolactinoma, nonfunctioning tumor) If positive family history, one of the above is needed to make the diagnosis. If negative family history, the presence of two of the above is necessary Other associated abnormalities: adrenocortical tumors, carcinoids, thyroid disorders
MEN IIa	Mutation of the *RET* protooncogene which is located on chromosome 10	Medullary cell carcinoma of the thyroid gland in 90% Phaeochromocytoma in 50% Hyperparathyroidism in 20%
MEN IIb	As MEN IIa	Medullary cell carcinoma in 98–100% Phaeochromocytoma in 50% Marfanoid habitus in 98–100% Multiple mucosal neuromas (e.g., lips and tongue) in 98–100% Gastrointestinal ganglioneuromas in 90% Hyperparathyroidism is rare

body weight, the adrenals are much larger at birth and weight about 8 grams (0.28 ounce). In adults, proportionately, the adrenals are 1/20th the size they are in infants. Most of the shrinkage in size and weight occurs during the first year of life. The adrenals are well supplied with blood and nerves.

While the adrenal glands perform a number of functions, the two most important are: (1) Control of the body's adjustment to an upright posture; and (2) accommodation of the body to intermittent rather than constant intake of food. The adrenals also participate importantly in the regulation of electrolyte and water balance; the activity of lymphoid tissue and the number of eosinophils circulating in the blood (see **Blood**); the response to stress situations as may be encountered in infection, anesthesia, surgery, and volume loss; and the secretion of hormones. These hormones influence immune reactivity, blood cell formation, cerebral function, protein synthesis, and numerous other body processes. See also **Endocrine System**; and **Hormones**.

Several serious problems occur when there is imbalance or dysfunction of the adrenal glands, as, for example, in hyperfunction of the adrenal cortex, which precipitates Cushing's syndrome, of which there are several sub-forms; in hypofunction of the adrenal cortex; in adrenal neoplasms; and in pheochromocytoma.

Adrenal Cortical Hormones

The hormones elaborated by the adrenal cortex are steroidal derivatives of cyclopentanoperhydrophenanthrene related to the sex hormones. The structural formulas of the important members of this group are shown in Fig. 1. With the exception of *aldosterone*, the compounds may be considered derivatives of *corticosterone*, the first of the series to be identified and named. The C_{21} steroids derived from the adrenal cortex and their metabolities are designated collectively as *corticosteroids*. They belong to two principal groups; (1) those processing an O or OH substituent at C_{11} (*corticosterone*) and an OH group at C_{17} (*cortisone* and *cortisol*) exert their chief action on organic metabolism and are designated as *glucocorticoids*; (2) those lacking the oxygenated group at C_{17} (*desoxycorticosterone* and *aldosterone*) act primarily on electrolyte and water metabolism and are designated as *mineralocorticoids*. In humans, the chief glucocorticoid is *cortisol*. The chief mineralocorticoid is *aldosterone*.

The *glucocorticoids* are involved in organic metabolism and in the organism's response to stress. They accelerate the rate of catabolism (destructive metabolism) and inhibit the rate of anabolism (constructive metabolism) of protein. They also reduce the utilization of carbohydrate and increase the rate of gluconeogenesis (formation of glucose) from protein. They also exert a lipogenic as well as lipolytic action, potentiating the release of fatty acids from adipose tissue. In addition to these effects on the organic metabolism of the basic foodstuffs, the glucocorticoids affect the body's allergic, immune, inflammatory, antibody, anamnestic, and general responses of the organism to environmental disturbances. It is these reactions which are the basis for the wide use of the corticosteroids therapeutically. See also **Immune System and Immunology**.

Aldosterone exerts its main action in controlling the water and electrolyte metabolism. Its presence is essential for the reabsorption of sodium by the renal tube, and it is the loss of salt and water which is responsible for the acute manifestations of adrenocortical insufficiency. The action of aldosterone is not limited to the kidney, but is manifested on the cells generally, this hormone affecting the distribution of sodium, potassium, water, and hydrogen ions between the cellular and extracellular fluids independently of its action on the kidney.

The differentiation in action of the glucocorticoids and the mineralocorticoids is not an absolute one. Aldosterone is about 500 times as effective as cortisol in its salt and water retaining activity, but is one-third as effective in its capacity to restore liver glycogen in the adrenalectomized animal. Cortisol in large doses, on the other hand, exerts a water and salt retaining action. Corticosterone is less active than cortisol as a glucocorticoid, but exerts a more pronounced mineralocorticoid action than does the latter. See also **Steroids**.

In addition to the aforementioned corticosteroidal hormones, the adrenal glands produce several oxysteroids and small amounts of testosterone and other androgens, estrogens, progesterone, and their metabolites.

Adrenal Medulla Hormones

Adrenaline (epinephrine) and its immediate biological precursor *noradrenaline* (*norepinephrine*, levarternol) are the principal hormones of the adult adrenal medulla. See Fig. 2. Some of the physiological effects produced by adrenaline are: contraction of the dilator muscle of the pupil of the eye (*mydriasis*); relaxation of the smooth muscle of the bronchi; constriction of most small blood vessels; dilation of some blood vessels, notably those in skeletal muscle; increase in heart rate and force of ventricular contraction; relaxation of the smooth muscle of the intestinal tract; and either contraction or relaxation, or both, of uterine smooth muscle. Electrical stimulation of appropriate sympathetic (*adrenergic*) nerves can produce all the aforementioned effects with exception of vasodilation in skeletal muscle.

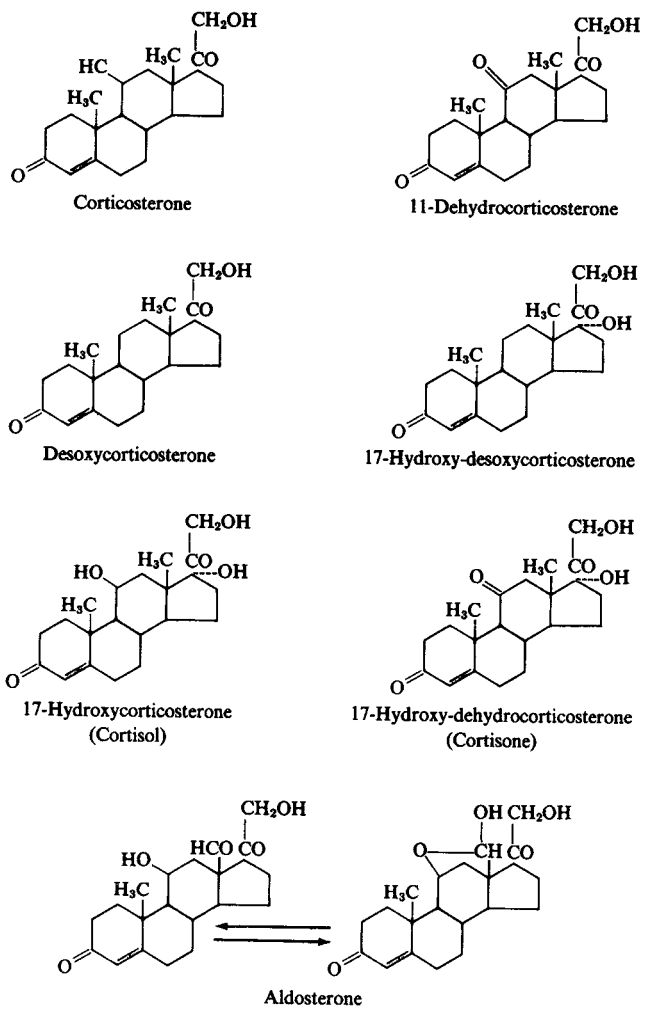

Fig. 1. Adrenal cortical hormones.

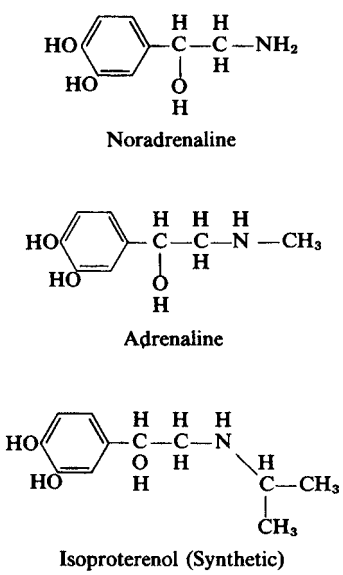

Fig. 2. Adrenal medula hormones.

Noradrenaline, when administered, produces the same general effects as adrenaline, but is less potent. Isoproternol, a synthetic analogue of noradrenaline, is more potent than adrenaline in relaxing some smooth muscle, producing vasodilation and increasing the rate and force of cardiac contraction.

Malfunctions of the Adrenals

Progressive destruction of the adrenal cortex, as found in *Addison's disease*, gives rise to symptoms resulting from deficiencies of the cortical hormones previously mentioned. In the Waterhouse-Friderichsen syndrome, destruction of part or the whole of one or both glands by hemorrhage, as may occur in the course of meningitis due to meningococci, leads to sudden collapse and death unless very prompt treatment by replacement of the absent hormones is available. See also **Addison's Disease**. In *Cushing's syndrome* (adrenal cortical excess), a rare condition, there is obesity of the abdomen, face, and buttocks, but not of the limbs. The skin about the face and hands is redder than normal. Hair grows profusely, and women may grow excessive hair about the face. Bones become brittle and suffer a considerable loss of mineral components. Sexual functions may fall to a low level. The adrenal cortex may be overly stimulated by an excess secretion of ACTH (*adrenocorticotropic hormone*) in the pituitary gland. See also **Pituitary Gland**. Also, excessive production of ACTH may be caused by malignant tumors, among which lung, thymus, pancreas, and kidney are the most common. Similar symptoms also may be produced by the excessive pharmacological (*iatrogenic*) use of steroids. Because of the multifaceted causes of Cushing's syndrome, differential diagnosis is important.

ADRENALINE AND NORADRENALINE. Noradrenaline (norepinephrine) is the main neurotransmitter of the sympathetic nervous system, and adrenaline (epinephrine) is the main hormone secreted by the adrenal medulla. Both compounds are catecholamines.

Introduction

Networks of sympathetic nerves have been recognized from antiquity. The term, *sympathetic nerve*, originated in the second century ideas of Galen, who taught that the chain of ganglia alongside the spinal column provided the medium for producing consent, or *sympathy*, among the body parts. In the early 1850s, Bernard and Brown-Sequard demonstrated the profound vascular effects of sympathetic nerve section and stimulation. By the beginning of the twentieth century, the anatomy and physiology of the sympathetic innervation of the heart had been described in detail. See also **Autonomic Nervous System**; and **Brown-Séquard, Charles Edouard (1817–1894)**.

The contribution of the adrenal medulla to circulatory function, however, remained unknown until 1895, when Oliver and Schafer reported the marked cardiovascular effects of injections of adrenal extracts. Soon afterwards, Abel identified the active principle of the adrenal extracts, adrenaline (epinephrine). Abel's 1902 report about adrenaline was the first to describe the synthesis of a hormone. About the same time, Takamine also isolated adrenaline from the adrenal gland.

American medical terminology uses Abel's appellation for the adrenomedullary hormone: epinephrine; British medical terminology, as here, uses Takamine's term: adrenaline. ("Adrenalin" is a registered trademark of Parke-Davis.)

Until about the turn of the twentieth century, the nervous and endocrine systems were thought to be distinct, with nervous impulses to and from skeletal muscle mediating interactions with the external environment, and with chemical substances transported in the bloodstream — hormones — determining the states of activity of internal organs. The work and ideas of Elliott and Loewi melded the neural and endocrine traditions in medicine. Elliott and his mentor, Langley, noted the similarity between the effects of adrenal extracts and those produced by stimulating sympathetic nerves. In 1904, Elliott proposed a revolutionary idea: a mechanism developed out of the muscle cell, in response to its union with the synapsing sympathetic fiber, the function of which is to receive and transform the nervous impulse. Adrenalin(e) might then be a chemical stimulant liberated on each occasion when the impulse arrives at the periphery [Elliott, 1904, p. xxi]. See also **Loewi, Otto (1873–1961)**.

Credit for the idea of chemical neurotransmission, a founding principle of neuropharmacology, goes to Elliott, for his explanation for the similarity between the effects of adrenaline and those of stimulating sympathetic nerves. See also **Neurotransmitters**.

Confirmation of adrenaline as both the adrenomedullary hormone and the sympathetic neurotransmitter would have led to a complete merger conceptually of the hormonal and neural adrenergic components, to form a single neuroendocrine system. In 1946, however, von Euler identified the neurotransmitter of the mammalian sympathetic nervous system as noradrenaline (norepinephrine), the precursor of adrenaline [von Euler, 1946].

On the basis of the influential experiments and writings of Walter B. Cannon, the "sympathico-adrenal" or "sympathoadrenal" system came to be considered to function as a unit, preserving homeostasis during exposure to extreme environmental or physiological stimuli and during "fight-or-flight" responses. Cannon coined both the terms "homeostasis" and "fight-or-flight." Later, Selye incorporated "adrenalines," a generic term for the catecholamines released from the adrenal medulla, in his concept of the "alarm" reaction, the first stage of the general adaptation syndrome [Selye, 1950]. See also **Cannon, Walter Bradford (1871–1945)**; and **Homeostasis**.

Numerous findings in neuroendocrinology, indicating complex interactions between nerves and hormones, have by now demonstrated the oversimplification in Cannon's and Selye's concepts [Goldstein, ref.]. In particular, accumulating evidence supports independent regulation of the sympathoneural and adrenomedullary systems, refuting the concept of a unitary sympathoadrenal system. Nevertheless, Cannon's views about the unitary function of the neural and hormonal components still prevail in research about the physiology of emergency reactions.

In response to perceived global, metabolic threats, whether from external or internal stimuli, increased neural outflow to the adrenal medulla elicits catecholamine secretion into the adrenal venous drainage. Adrenaline therefore rapidly reaches all cells of the body (with the exception of most of the brain), producing a wide variety of hormonal effects at low blood concentrations. One can comprehend all the many effects of adrenaline in terms of countering acute threats to survival that mammals have perennially faced, such as sudden lack of metabolic fuels, trauma with hemorrhage, intravascular volume depletion and hypotension, and fight-or-flight confrontations. Thus, even mild hypoglycemia elicits marked increases in plasma levels of adrenaline. Distress accompanies all these situations, the experience undoubtedly fostering the long-term survival of the individual and the species by motivating avoidance learning and producing signs universally understood among other members of the species.

In contrast, the sympathetic nervous system provides a nerve network for regional alterations in vascular tone and glandular secretion. During orthostasis, after eating a meal, during exposure to altered environmental temperature, or during mild or moderate amounts of exercise, redistributions of blood flow and glandular (sweat, salivary) secretion suffice to maintain the internal environment. In these situations, the organism usually does not feel distressed.

Largely due to Cannon, the view has persisted that despite the importance of the sympathetic nervous and adrenomedullary hormonal systems in maintaining homeostasis during emergency situations, the maintenance of vital functions under resting conditions does not require these systems. Thus, within the sheltered confines of a laboratory, animals that have undergone extensive surgical sympathectomies seem entirely normal.

Cannon did not consider the possibility that loss of the sympathetic nervous system would lead to compensatory recruitment of the adrenomedullary hormonal system, or that destruction of both systems would compensatorily activate other effector systems. Whereas in anaesthetized animals, clamping of the adrenal hilar vessels — which eliminates adrenomedullary secretion — does not change blood pressure, the same clamping in chemically sympathectomized animals produces rapid decreases in blood pressure to shock levels, indicating a compensatory

interaction between the sympathetic nervous system and adrenomedullary hormonal system in tonic regulation of blood pressure. Administration of an angiotensin II antagonist or angiotensin-converting enzyme inhibitor or arginine vasopressin antagonist to sympathectomized animals also produces hypotension. The sympathetic nervous system therefore plays a key role not only in circulatory responses during emergency reactions but also in maintaining tonic levels of cardiovascular performance. Sympathetic ablation compensatorily activates other vasoactive systems, including the adrenomedullary hormonal system, renin-angiotensin-aldosterone system, and the arginine vasopressin system, masking the role of the sympathetic nervous system.

Noradrenaline: The Sympathetic Neurotransmitter

Enzymatic steps in noradrenaline synthesis have been characterized in more detail than those for any other neurotransmitter (Figs. 1 and 2). Catecholamine biosynthesis begins with uptake of the amino acid tyrosine into the cytoplasm of sympathetic neurons, adrenomedullary cells, possibly para-aortic enterochromaffin cells, and specific centers in the brain. Circulating tyrosine derives from the diet and from hepatic hydroxylation of phenylalanine. See also **Amino Acids**.

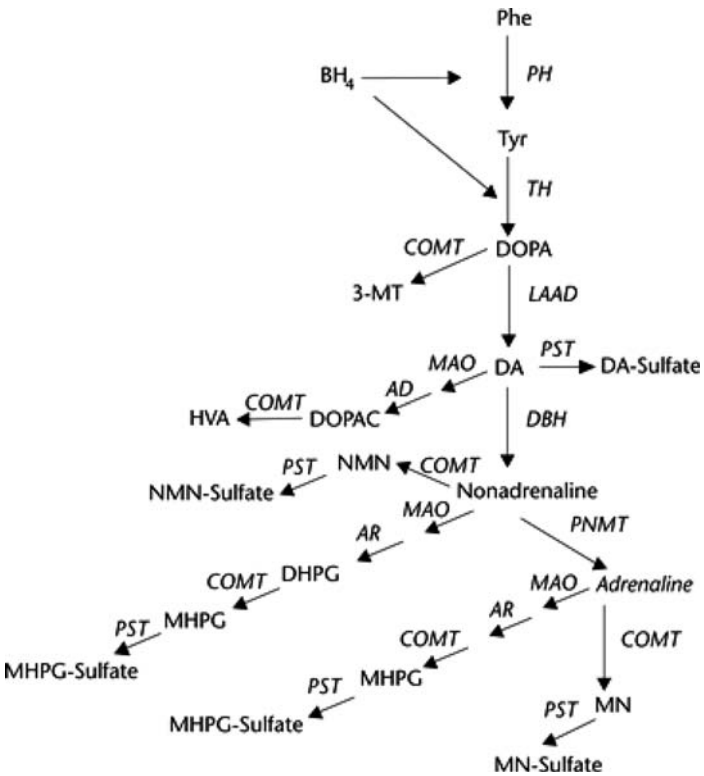

Fig. 1. Overview of catecholamine synthetic and metabolic pathways. Note single pathway of catecholamine synthesis, via hydroxylation of tyrosine and decarboxylation of L-DOPA, compared with multiple pathways of catecholamine metabolism. Abbreviations: BH_4, tetrahydrobiopterin; Phe, phenylalanine; PH, phenylalanine hydroxylase; Tyr, tyrosine; TH, tyrosine hydroxylase; COMT, catechol *O*-methyltransferase; PST, phenylsulfotransferase; 3-MT, 3-methoxytyrosine; LAAD, L-aromatic-amino-acid decarboxylase; DA, dopamine; MAO, monoamine oxidase; AD, aldehyde dehydrogenase; AR, aldehyde reductase; DBH, dopamine-β-hydroxylase; PNMT, phenylethanolamine *N*-methyltransferase; NMN, normetanephrine; MN, metanephrine; DHPG, dihydroxyphenylglycol; MHPG, methoxyhydroxyphenylglycol; VMA, vanillylmandelic acid; DOPAC, dihydroxyphenylacetic acid; HVA, homovanillic acid.

Tyrosine hydroxylase (EC 1.14.16.2: http://www.expasy.ch/cgi-bin/nicezyme.pl?1.14.16.2) catalyses the conversion of tyrosine to l-dihydroxyphenylalanine (l-DOPA). This is the enzymatic rate-limiting step in catecholamine synthesis. Tetrahydrobiopterin, Fe^{2+}, and molecular oxygen are required for tyrosine hydroxylase activity. Exposure to stressors that increase sympathetic and adrenomedullary outflows augments the synthesis and concentration of tyrosine hydroxylase.

l-Aromatic-amino-acid decarboxylase (also called *DOPA decarboxylase*) (EC 4.1.1.28: "http://www.expasy.ch/cgi-bin/nicezyme.pl?4.1.1.28) in the

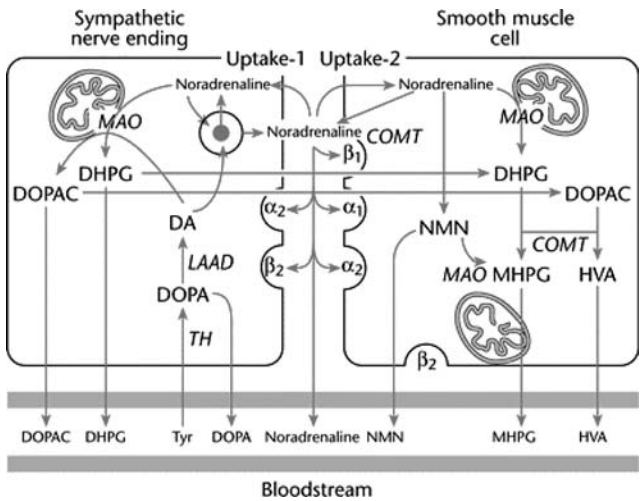

Fig. 2. Overview of steps in noradrenaline synthesis, release, reuptake, and metabolism. Abbreviations as in Fig. 1.

neuronal cytoplasm catalyses the rapid conversion of l-DOPA to dopamine. Many tissues contain this enzyme — especially the kidneys, gut, liver, and brain. The enzyme uses pyridoxal phosphate as a cofactor.

Dopamine β-hydroxylase (EC 1.14.17.1: http://www.expasy.ch/cgi-bin/nicezyme.pl?1.14.17.1) catalyses the conversion of dopamine to noradrenaline. The enzyme is confined to vesicles in catecholamine-synthesizing cells. Thus, treatment with reserpine, which blocks the translocation of amines from the axonal cytoplasm into vesicles, prevents the conversion of dopamine to noradrenaline in sympathetic nerves and depletes noradrenaline stores. Dopamine β-hydroxylase contains, and its activity depends on, copper. Activity of the enzyme also requires ascorbic acid (vitamin C).

Phenylethanolamine *N*-methyltransferase (EC 2.1.1.28: http://www.expasy.ch/cgi-bin/nicezyme.pl?2.1.1.28) catalyses the conversion of noradrenaline to adrenaline in chromaffin cells.

Agonist occupation of nicotinic acetylcholine receptors releases catecholamines from the cells. Since nicotinic receptors mediate ganglionic neurotransmission, researchers have presumed that the results obtained in adrenomedullary cells probably apply to postganglionic sympathoneural cells. According to the exocytotic theory of noradrenaline release, acetylcholine depolarizes the terminal membranes by increasing membrane permeability to sodium. The increased intracellular sodium levels directly or indirectly enhance transmembrane influx of calcium, via voltage-gated calcium channels. The increased cytoplasmic calcium concentration evokes a cascade of as yet incompletely defined biomechanical events result in fusion of the vesicular and axoplasmic membranes. The interior of the vesicle exchanges briefly with the extracellular fluid compartment, and the soluble contents of the vesicles diffuse into the extracellular space.

Pharmacological stimulation of a large variety of receptors on noradrenergic terminals affects the amount of noradrenaline released during cellular activation. In general, it remains unproven whether at physiological concentrations these compounds exert modulatory effects on endogenous noradrenaline release, especially in humans. However, substantial evidence does support inhibitory presynaptic modulation by noradrenaline itself, via autoreceptors on sympathetic nerves.

In addition to local feedback control of noradrenaline release, reflexive "long-distance" feedback pathways, via high- and low-pressure baroreceptors, elicit reflexive changes in sympathoneural impulse activity. Alterations in receptor numbers or of intracellular biomechanical events after receptor activation also affect responses to agonists. These factors may therefore regulate noradrenaline release by transsynaptic local and reflexive long-distance mechanisms.

Unlike acetylcholine, which is inactivated mainly by extracellular enzymes, noradrenaline is inactivated mainly by uptake into cells, with subsequent intracellular metabolism or storage. Reuptake into nerve terminals — Uptake-1 — is the predominant means of terminating the actions of released noradrenaline. Uptake-1 is energy-requiring and carrier-mediated. Uptake-1 does not require a catechol nucleus, since drugs that have only one phenolic hydroxyl group are substrates for Uptake-1. Alkylation of the

primary amino group decreases the effectiveness of the transport, explaining why sympathetic nerves take up noradrenaline more efficiently than they do adrenaline and why they do not take up isoproterenol, an extensively alkylated catecholamine, at all. Many drugs or *in vitro* conditions inhibit Uptake-1, including cocaine, tricyclic antidepressants, low extracellular Na^+ concentrations, and nitrogen mustards.

Noradrenaline taken up into the axoplasm by the Uptake-1 transporter is subject to two fates: translocation into storage vesicles and deamination by monoamine oxidase. The combination of enzymatic breakdown and vesicular uptake constitutes an intraneuronal "sink," keeping cytoplasmic concentrations of noradrenaline very low.

Neural and nonneural tissues contain monoamine oxidase (EC 1.4.3.4: http://www.expasy.ch/cgi-bin/nicezyme.pl?1.4.3.4), which catalyses the oxidative deamination of all catecholamines. Because of the efficient uptake and reuptake of catecholamines into the axoplasm of catecholaminergic neurons, and because of the rapid exchange of amines between the vesicles and axoplasm, the neuronal pool of monoamine oxidase, located in the outer mitochondrial membrane, figures prominently in the overall functioning of catecholaminergic systems.

Monoamine oxidase inhibitors are effective antidepressants. A phenomenon known as the "cheese effect" limits their clinical use. In patients taking monoamine oxidase inhibitors, administration of sympathomimetic amines such as in many nonprescription decongestants or ingestion of foods that contain tyramine can produce paroxysmal hyper tension. Tyramine displaces noradrenaline from sympathetic vesicles into the axoplasm, and blockade of monoamine oxidase in this setting causes axoplasmic noradrenaline to accumulate. Outward transport of the noradrenaline stimulates cardiovascular smooth-muscle cells, producing intense vasoconstriction and hypertension. See also **Hypertension**.

Nonneuronal cells remove noradrenaline by a process called Uptake-2. The Uptake-2 carrier has low affinity and specificity for catecholamines. For instance, extraneuronal cells remove imidazolines such as clonidine by Uptake-2. Whereas reverse transport via the Uptake-1 carrier requires special experimental conditions, one can readily demonstrate reverse transport via the Uptake-2 carrier.

Catechol *O*-methyltransferase (EC 2.1.1.6: http://www.expasy.ch/cgi-bin/nicezyme.pl?2.1.1.6) catalyses the conversion of noradrenaline to normetanephrine and adrenaline to metanephrine. Uptake-2 and catechol *O*-methyltransferase probably act in series to remove and degrade circulating catecholamines. The methyl group donor for the reaction is *S*-adenosylmethionine. *O*-Methylation of catecholamines outside the adrenal glands requires extraneuronal uptake.

Vanillylmandelic acid and methoxyhydroxyphenylglycol, the products of the combined *O*-methylation and deamination of noradrenaline, are the two main end products of noradrenaline metabolism, with vanillylmandelic acid formed mainly in the liver.

Adrenaline: The Adrenomedullary Hormone

Adrenaline, the main adrenomedullary hormone in humans, affects the function of virtually all body organs. Adrenomedullary secretion of adrenaline figures prominently in neuroendocrine patterns attending distress.

Much more is known about the physiological effects of endogenous adrenaline than of endogenous noradrenaline. This is because adrenaline acts mainly as a hormone in the body and has a single main source — the adrenal medulla — whereas noradrenaline acts mainly as a neurotransmitter in the body, and plasma noradrenaline derives from myriad sympathetic nerve endings in organs and glands. See also **Adrenal Disease**; and **Adrenal Glands**.

Glucocorticoids, present at high concentrations due to the corticomedullary direction of blood flow, regulate adrenal phenylethanolamine *N*-methyltransferase activity. An intrinsic genetic component probably also regulates adrenal adrenaline synthesis.

According to the "adrenaline hypothesis," sympathetic nerve terminals take up circulating adrenaline by Uptake-1; sympathetic stimulation coreleases the removed adrenaline with noradrenaline; coreleased adrenaline binds to β-adrenoceptors on sympathetic terminals; and binding of coreleased adrenaline to β-adrenoceptors augments further noradrenaline release. This hypothesis provides a model in which endogenous compounds taken up into neuronal terminals are coreleased with the transmitter and prolong or exaggerate release of the neurotransmitter by binding to facilitatory presynaptic receptors. Studies designed to test the adrenaline hypothesis comprehensively in isolated tissue preparations, and recently in humans, have failed to confirm it.

Physiological Effects of Catecholamines

Ahlquist [1948] proposed a basis for different cardiovascular effects of noradrenaline and adrenaline — that these catecholamines differentially stimulate specific receptors, adrenergic receptors or adrenoceptors. Ahlquist suggested two types of adrenoceptors, α and β.

Adrenoceptors in the membranes of effector cells determine the physiological and metabolic effects of catecholamines. Adrenaline stimulates both types of receptor, whereas noradrenaline stimulates α-adrenoceptors preferentially.

In general, β-adrenoceptors mediate the positive inotropic and chronotropic effects of catecholamines in the heart; stimulation of vascular α-adrenoceptors produces vasoconstriction; and stimulation of vascular β-adrenoceptors — especially in skeletal muscle — produces vasodilation. Non-specific α-blockers include ***phenoxybenzamine*** and ***phentolamine***, nonspecific β-blockers include ***propranolol*** and ***timolol***; non-specific α-agonists include ***noradrenaline***; and non-specific β-agonists include isoproterenol.

β-Adrenoceptors have been classified further into β_1, β_2 and β_3 subtypes. Adrenaline has about 20 times greater potency than noradrenaline at β_2-adrenoceptors. β_1-Selective antagonists, including ***atenolol*** and ***metoprolol***, are used to treat angina pectoris, hypertension, and some arrhythmias. β_2-Selective agonists, including ***terbutaline***, ***salbutamol***, ***albuterol*** and ***metaproterenol***, are used to treat asthma. The β_3-adrenoceptor seems to participate in lipolytic effects of catecholamines.

α_2-Adrenoceptors in the periphery are located presynaptically and extrasynaptically and can exert either stimulatory or inhibitory effects, depending on the cell type on which they are located. Thus, occupation of α_2-adrenoceptors on vascular smooth-muscle cells elicits muscular contraction, whereas occupation of α_2-adrenoceptors on sympathetic nerve terminals inhibits exocytotic release of noradrenaline. Stimulation of either α_1-receptors or α_2-receptors on vascular smooth-muscle cells elicits vasoconstriction. There is no convincing evidence for presynaptic α_1-adrenoceptors.

α_1-Selective agonists include ***phenylephrine*** and ***methoxamine*** and α_1-selective antagonists include ***prazosin*** and ***terazosin***. α_2-Selective agonists include ***clonidine***, ***guanfacine***, ***guanabenz*** and ***α-methylnoradrenaline***; α_2-selective antagonists include ***yohimbine***, ***rauwolscine***, and ***idazoxan***. Whether the presynaptic α_2-adrenoceptors are structurally unique is unknown.

In the intact organism, β-adrenoceptors mediate most of the cardiac effects of catecholamines. Human myocardium has similar concentrations of β_1- and β_2-adrenoceptors. In humans, adrenaline is probably not the main endogenous catecholamine acting at cardiac adrenoceptors, because interstitial fluid noradrenaline concentrations probably far exceed those of adrenaline, and noradrenaline is an agonist at β_1-adrenoceptors. Stimulation of cardiac β-adrenoceptors of both subtypes increases cardiac contractility, rate and electrical automaticity. The β_2-adrenoceptor subtype appears to predominate in vascular smooth-muscle cells and on vascular sympathetic nerve terminals. Most cardiac α-adrenoceptors are of the α_1 subtype.

In skeletal muscle, β_2-, α_1- and α_2-adrenoceptors contribute to the regulation of regional vascular resistance. Administration of adrenaline, an agonist at all these receptors, decreases skeletal muscle vascular resistance because of the prominent stimulation of extrasynaptic β_2-adrenoceptors.

Membrane receptors transmit information via signal-transducing G proteins (guanine-nucleotide regulatory proteins), located near the receptor on the inner portion of the cell membrane. Details of the intracellular cascade upon activation of G-proteins have been studied extensively for β-adrenoceptors. G_s is the G-protein responsible for cellular activation upon occupation of β-adrenoceptors. The G protein complex consists of an α subunit, responsible for the specificity of the G protein, and β and γ subunits. The heterotrimeric G proteins constitute a "superfamily," with many different α subunits and at least two different β and γ subunits. A large variety of receptors appear to work by way of stimulatory or inhibitory G proteins.

Cyclic adenosine monophosphate, cAMP, an intracellular "second messenger" (the first messenger being the hormone binding to the receptor), stimulates cAMP-dependent protein kinase. This leads to phosphorylation of many proteins, evoking changes in cellular activity such as contraction or secretion.

Agonist occupation of α_1-adrenoceptors leads to a different cascade of intracellular events from that consequent to agonist occupation of β-adrenoceptors. The α_1-adrenoceptor is linked to a different G-protein, G_p. Occupation of the receptor by the agonist leads to activation of the G protein by GTP hydrolysis. This activates phospholipase C, which catalyses the hydrolysis of phosphatidylinositol 4,5-bisphosphate to form two active subunits, inositol trisphosphate and diacylglycerol. Diacylglycerol activates protein kinase C, leading to cellular activation. Meanwhile, inositol trisphosphate binds to another receptor on the endoplasmic reticulum, releasing Ca^{2+} from the stores into the cytoplasm, also activating the cell.

Agonist occupation of α_2-adrenoceptors inhibits adenyl cyclase by interaction with an inhibitory G protein, G_i.

Cannon was probably the first to describe in detail the enhancement of responses to catecholamines after section of the sympathetic nerve supply [Cannon, 1939a]. Most research on the basis for "denervation supersensitivity" has focused on changes in the numbers of available adrenoceptors, with relatively little attention to intracellular mechanisms.

The terms *upregulation* and *downregulation* have been used to describe changes in both the numbers of membrane-bound receptors, as quantified from ligand-binding studies, and changes in total numbers of receptors in the cells. One can readily demonstrate desensitization of β-adrenoceptor-mediated responses in *in vitro* preparations, and a large body of research has concentrated on mechanisms of this phenomenon. Relatively few studies have concentrated on desensitization of responses mediated by α-adrenoceptors.

Homologous desensitization refers to a situation in which production of an intracellular second messenger, such as cAMP, decreases in response to stimulation of specific receptors but not in response to stimulation of other receptors using the same second messenger. Homologous desensitization is therefore agonist-specific. Heterologous desensitization entails attenuated responses to all agonists using the same second messenger. Heterologous desensitization is therefore agonist-nonspecific. Several mechanisms of homologous desensitization have been proposed, and whereas evidence for each has been obtained in *in vitro* systems, the roles of these mechanisms *in vivo* is incompletely understood. Desensitization of β-adrenoceptor-mediated responses is thought to occur in three sequential steps: uncoupling of the receptor from the G_s protein, a process associated with decreased affinity for β-agonists; internalization of the receptor, with reversible loss of receptors at the membrane; and downregulation, an only slowly reversible loss of the total number of functional receptors in the cell.

Catecholamines affect cardiovascular function by at least three general mechanisms: actions at cardiovascular adrenoceptors, eliciting changes in cardiac and vascular function directly; actions in the nervous system, influencing sympathoneural and adrenomedullary outflows and activities of several other stress systems of the body; and actions in the kidney, affecting renal handling of sodium and thereby blood volume and pressure. Circulatory effects of adrenaline include increased cardiac output, which enhances delivery of oxygen and glucose throughout the body; redistribution of blood volume to the cardiopulmonary area, which preserves perfusion of the heart and brain; and increased skeletal muscle vasodilation and cutaneous, renal, and splanchnic vasoconstriction, which support increased skeletal metabolism during "fight or flight" behaviors. Adrenaline induces relatively small changes in pulmonary, cerebral and coronary vascular resistance, due to complex interactions between adrenoceptor-mediated actions and effects of alterations in myocardial metabolism. Systemic injection of noradrenaline produces virtually universal vasoconstriction. The increased blood pressure stimulates arterial baroreceptors, and heart rate tends to decrease reflexively. Thus, although in suitable preparations stimulation of α-adrenoceptors increases cardiac contractility, baroreflexes usually mask the cardiac effects of injected α-adrenoceptor agonists. Cardiac responses to circulating adrenaline resemble those to cardiac sympathetic stimulation: tachycardia related to increased sinoatrial node automaticity, increased cardiac contractility, accelerated atrioventricular conduction, decreased refractory periods, and decreased thresholds for ventricular arrhythmias. See also **Arrhythmias (Cardiac)**.

Sympathoneural stimulation augments renal sodium retention, by several mechanisms. Renal vasoconstriction decreases local perfusion and thereby decreases glomerular filtration of sodium. Stimulation of renal β_1-adrenoceptors increases secretion of renin, increasing production of angiotensin II, which both acts as a potent vasoconstrictor and also augments adrenocortical secretion of aldosterone, the latter inducing Na^+-K^+ exchange in the kidneys and causing further retention of sodium. Finally, noradrenaline can exert an antinatriuretic effect by direct actions at renal tubular cells.

Catecholamines generally inhibit gut motility and suspend digestive processes. The usually concurrent splanchnic vasoconstriction shunts blood to the heart, lungs, brain, and skeletal muscle. Cannon showed that the adrenal effluent and adrenaline itself relax intestinal muscle. Indeed, the prominent relaxation of intestinal muscle by adrenaline in bioassays provided the basis for the first demonstration that emotional stress increases adrenal release of adrenaline [Cannon and de la Paz, 1911]. Both α- and β-adrenoceptors mediate the gastrointestinal inhibition.

Pallor, cyanosis, sweating, shivering and piloerection caused by sympathoneural stimulation constitute major signs of emotional distress and shock. Administration of both noradrenaline and adrenaline produces cutaneous vasoconstriction, due to stimulation of α_1- and α_2-adrenoceptors on vascular smooth-muscle cells. Sympathetic cholinergic stimulation of eccrine glands induces thermoregulatory sweating. In contrast with skeletal sympathoneural activity, which is especially responsive to alterations in baroreflex activity, cutaneous sympathoneural activity is responsive to emotional stressors and to alterations in environmental temperature. Facial sweating and flushing associated with body heating or embarrassment depend importantly on active, postganglionic sympathetic innervation. Sympathetic vasodilator fibers seem to accompany sudomotor and vasoconstrictor fibres to the face.

Catecholamine-induced thermogenesis probably results from the lipolytic effect of β-adrenoceptor agonism. Since physiological increments in plasma adrenaline levels increase metabolic rate, endogenous adrenaline may participate in maintenance of body weight.

Adrenaline decreases the serum potassium concentration, by a mechanism dependent on β_2-adrenoceptors. The effect occurs independently of insulin, aldosterone, and renal function.

Complex interactions among thyroid hormones and the sympathoneural and adrenomedullary systems probably determine basal metabolic rate. Hyperthyroidism often presents clinically with signs of cardiovascular sympathetic stimulation, including tachycardia, systolic hypertension, and arrhythmias, perhaps because thyroid hormone increases the numbers of myocardial β-adrenoceptors. Thyroidectomy augments plasma noradrenaline responses to exposure to cold in laboratory animals.

Cannon wrote that adrenaline release during stress promotes hemostasis, not only by vasoconstriction but also by accelerated blood clotting [Cannon, 1939b]. These effects would have afforded an adaptive advantage in evolution, by minimizing hemorrhage after trauma. Adrenaline and noradrenaline both cause platelet aggregation (adrenaline is more potent). The concentration of adrenaline required to produce platelet aggregation directly *in vitro* is much higher than the endogenous concentration. The combination of adrenaline *in vitro* with other agents that activate platelets (e.g. thrombin, collagen, adenosine diphosphate, vasopressin), however, markedly decreases adrenaline concentrations required to induce platelet aggregation. Thus, during stress responses involving activation of several neuroendocrine systems simultaneously, relatively small increases in circulating adrenaline levels may enhance platelet aggregability. The mechanism of adrenaline-induced platelet aggregation is thought to be via stimulation of α_2-adrenoceptors. See also **Blood Clotting: General Pathway**; and **Platelets**.

Exogenously administered catecholamines induce a lymphocytosis, a phenomenon opposite to that produced by exogenously administered corticosteroids. In laboratory animals, sympathetic stimulation contracts the spleen. Splenic contraction expands circulating blood volume and therefore aids in countering effects of traumatic hemorrhage. Adrenaline-induced vasoconstriction slows the microcirculation in injured regions. This fosters the adhesion of leucocytes to the vascular endothelium ("pavementing"); leucocytes migrate through small blood vessel walls within a few minutes of injury. See also **Spleen**.

Because of the effective blood-brain barrier for catecholamines, circulating catecholamines do not reach most adrenoceptors in the central nervous system. See also **Blood-Brain Barrier**.

Many behavioral effects of adrenaline have been described, including anxiety, increased alertness, trembling and an energizing effect, with decreased muscular and psychological fatigue. Adrenaline increases the intensity of mental concentration and enhances performance of perceptual-motor tasks, despite adrenaline-induced tremor. Adrenaline also enhances emotional experiences. Cannon described the antifatigue effect of adrenaline in preparations of skeletal and cardiac muscle. The mechanism

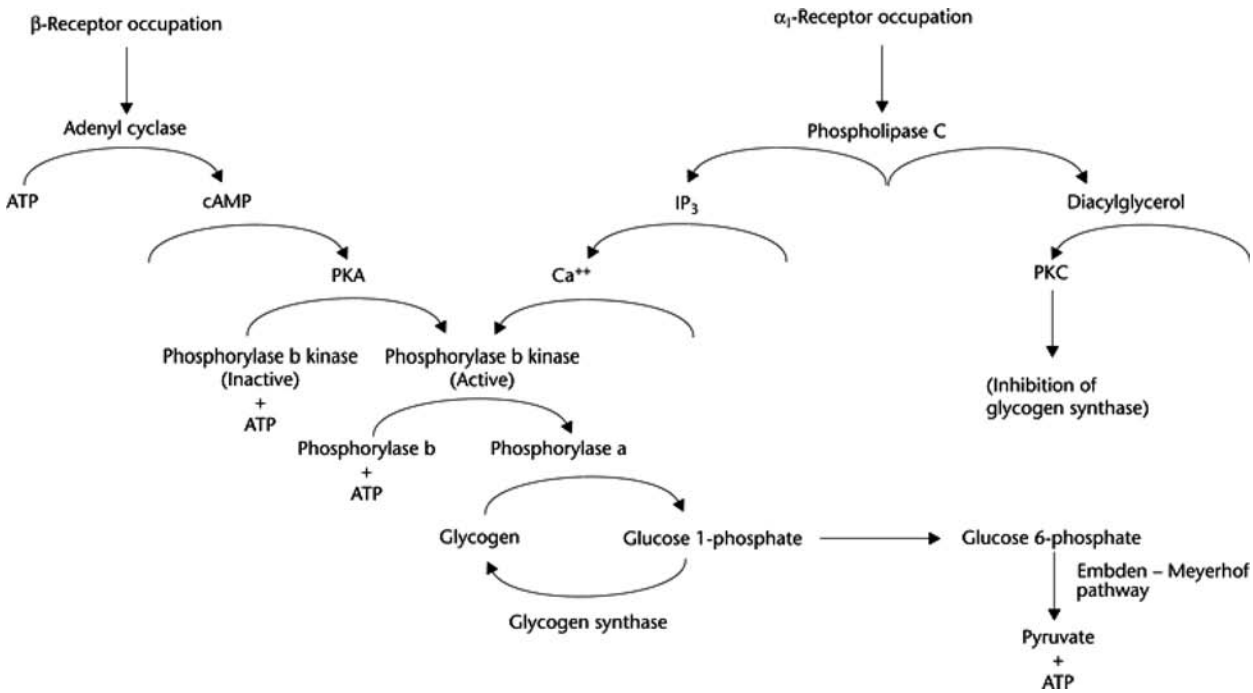

Fig. 3. Pathways of catecholamine-induced glycogenolysis. In the liver, adrenaline and glucagon liberate energy by stimulating the catabolism of glycogen via the enzyme phosphorylase. Activation of phosphorylase by adrenaline, after binding of adrenaline to β_2-adrenoceptors on liver cells, depends on formation of cyclic adenosine monophosphate (cAMP) inside the cells. Cellular activation by phosphorylation also depends on hormonal effects of adrenaline in the liver. cAMP activates protein kinase A (PKA), which in turn catalyses the production of activated phosphorylase b kinase from inactive phosphorylase b kinase and adenosine triphosphate (ATP). Activated phosphorylase b kinase in turns catalyses the production of phosphorylase a from inactive phosphorylase b and ATP. Finally, phosphorylase a catalyses the breakdown of glycogen to glucose 1-phosphate and the generation of energy in the form of ATP. Stimulation of α_1-adrenoceptors in the liver also leads to glycogen breakdown via phosphorylase kinase and inhibition of glycogen synthase, by mechanisms independent of cAMP.

of the antifatigue effect of adrenaline, and more generally the basis for antifatigue effects of emotion, are poorly understood. Learning of appetitive or avoidance behaviors requires recollection of pleasurable and painful experiences. The long-term potentiation of excitatory synaptic inputs in the brain has provided the basis for a cellular model of learning and memory. Depletion of noradrenaline in the brain blocks this long-term potentiation.

The iris possesses high concentrations of catecholamine-fluorescent terminals. The radial muscle contains both α- and β-adrenoceptors. β-Adrenergic blockade produces pupillary constriction.

Pulmonary effects of adrenaline include bronchiolar dilation and hyperventilation. Clinicians exploit the former effect when they inject adrenaline to abort asthma attacks; and sudden awakening by a noise increases the rate of breathing within a few seconds. The mechanism of ventilatory stimulation by adrenaline is unknown. The suggestion that adrenaline directly stimulates a medullary centre regulating ventilation must take into account the blood-brain barrier for adrenaline. Perhaps blood-borne catecholamines reach medullary sites via the area postrema, a circumventricular organ lacking a blood-brain barrier. See also **Asthma**.

Effects of Adrenaline on the Liver

The stimulatory effect of adrenaline on release of glucose by the liver was one of the first discovered actions of a hormone. Cannon [1929] conceptualized a vagal-pancreatic insular inhibitory and a sympathico-adrenal stimulatory system regulating blood glucose-one of the earliest descriptions of opposing neuroendocrine patterns. He also demonstrated the inhibitory effect of vagal stimulation on blood sugar, indicating cholinergic stimulation of pancreatic insulin secretion.

Administration of adrenaline increases blood glucose concentrations by stimulating hepatic gluconeogenesis and glycogenolysis, increasing secretion of glucagon, and inhibiting insulin secretion by the pancreas (Fig. 3). This provides "instant energy" for nervous tissue. See **Insulin and Glucagon**.

By opposing effects of insulin on glucose uptake, and inhibiting insulin secretion, adrenaline administration increases circulating glucose levels. Adrenaline indirectly increases gluconeogenesis, by increasing lactate production in skeletal muscle, in turn increasing conversion of circulating lactate to glucose in the liver.

Studies about the mechanisms of the glycogenolytic effect of adrenaline in the liver have led to key concepts in pharmacology. The discovery of cAMP and of the role of phosphorylation in activating and deactivating enzymes depended on adrenaline-induced glycogenolysis. Generation of cAMP activates protein kinase A, and this simultaneously increases glycogen breakdown, via increased production of phosphorylase a, and decreases glycogen synthesis, via inhibition of production of glycogen synthase I.

Hepatic parenchymal cells possess sympathetic innervation, suggesting that both hormonal adrenaline and neuronal noradrenaline may contribute to glycogenolysis. In humans, α_1- and β_2-adrenoceptors appear to contribute to adrenaline-induced glycogenolysis.

Three hormones — insulin, glucagon and adrenaline — dominate in glucose homeostasis. In patients with insulin-dependent diabetes mellitus, the glucagon response to hypoglycemia is lost at an early stage of the disease. As a result, adrenaline plays a key role in glucose counterregulation and in the defense of blood glucose in response to insulin overdose in these patients. Adrenaline also rapidly increases plasma levels of free fatty acids. This provides 'instant energy' for skeletal muscle. Increased adrenaline secretion explains the increases in free fatty acid levels associated with emotional distress. Theoretically, excess free fatty acids can be transformed to triglycerides in the liver, explaining increases in triglyceride levels associated with emotion. ADRET. The slope (usually equatorward, or southward in the Northern Hemisphere) of a mountain that faces into the sun. The term is originally and most often used in referring to mountains in the Alps. Tilted toward the sun, an adret is characterized by higher temperatures, a longer growing season, less snow cover and a shorter duration of snow cover, and a higher timber line and snow line than the shaded side (the ubac).

ADRIAN, EDGAR DOUGLAS (1889–1977). Edgar Adrian was an English physiologist and one of the founders of modern neurophysiology. Born in London, Adrian trained in the Physiological Laboratory, Cambridge and St Bartholomew's Hospital, London. After working in clinical neurology during World War I he returned to Cambridge in 1919 where he remained for the rest of his life. A Trinity College Lectureship in Natural Science was followed by a University Lectureship in the Physiological Laboratory, and in 1929 he was appointed a Foulerton Research Professor of the Royal Society, succeeding Sir Joseph Barcroft as Professor of Physiology in 1937. In 1951 he resigned his Chair to become Master of Trinity College. See also **Barcroft, Joseph (1872–1947)**.

As an undergraduate Adrian had been much influenced by the neurophysiologist Keith Lucas. In 1919 he began to study the recovery of nerve and muscle fibres after excitation and developed a technique, using triode valves, of amplifying the very small electrical signals generated by such material. In collaboration with other scientists he recorded the electrical activity of single, isolated nerve fibres, from both sensory and subsequently motor, nerves, and showed that there is only one kind of nervous impulse. That is, neural information is conveyed by variations in the frequency at which the impulses are transmitted, the so-called 'frequency code' which is a fundamental characteristic of all nerves. Either alone or with collaborators he also studied the physiology of sense organs in a wide variety of different species by investigating the mechanisms of peripheral functioning of receptors and sense organs in response to a stimulus, and then following the processes of information transmission into the central nervous system, where he investigated the recording and analysing of sensory information. In 1934 Adrian also confirmed and extended earlier observations of other scientists, of the gross electrical activity of the human brain, electroencephalography (EEG). The methodology and interpretation of EEGs has since developed into an important tool for the study of cerebral activity and diseases such as epilepsy. Adrian was elected a Fellow of the Royal Society in 1923 and served as Foreign Secretary from 1945 to 1950 and as President from 1950 to 1955. In 1932 he shared the Nobel Prize in Physiology or Medicine with fellow British physiologist Sir Charles Sherrington for their discoveries regarding the function of the nervous system. See also **Sherrington, Charles Scott (1857–1952)**.

ADSORPTION: GAS SEPARATION. Gas-phase adsorption is widely employed for the large-scale purification or bulk separation of air, natural gas, chemicals, and petrochemicals. In these uses it is often a preferred alternative to the older unit operations of distillation and absorption.

An adsorbent attracts molecules from the gas, and the molecules become concentrated on the surface of the adsorbent and are removed from the gas phase. Many process concepts have been developed to allow the efficient contact of feed gas mixtures with adsorbents to carry out desired separations and to allow efficient regeneration of the adsorbent for subsequent reuse. In nonregenerative applications, the adsorbent is used only once and is not regenerated.

Most commercial adsorbents for gas-phase applications are employed in the form of pellets, beads, or other granular shapes, typically about 1.5 to 3.2 mm in diameter. Most commonly, these adsorbents are packed into fixed beds through which the gaseous feed mixtures are passed. Normally, the process is conducted in a cyclic manner. When the capacity of the bed is exhausted, the feed flow is stopped to terminate the loading step of the process, the bed is treated to remove the adsorbed molecules in a separate regeneration step, and the cycle is then repeated.

The growth in both variety and scale of gas-phase adsorption separation processes, particularly since 1970, is due in part to continuing discoveries of new porous, high surface-area adsorbent materials (particularly molecular sieve zeolites) and, especially, to improvements in the design and modification of adsorbents. These advances have encouraged parallel inventions of new process concepts. Increasingly, the development of new applications requires close cooperation in adsorbent design and process cycle development and optimization.

Adsorption Principles

The design and manufacture of adsorbents for specific applications involves manipulation of the structure and chemistry of the adsorbent to provide greater attractive forces for one molecule compared to another, or, by adjusting the size of the pores, to control access to the adsorbent surface on the basis of molecular size. Adsorbent manufacturers have developed many technologies for these manipulations, but they are considered proprietary and are not openly communicated. Nevertheless, the broad principles are well known and involve adsorption forces, selectivities, and heat of absorption.

Isotherm Models models include both the statistical thermodynamic models and the models that can be derived from an assumed equation of state for the adsorbed phase plus the thermodynamics of the adsorbed phase.

To permit the recovery of pure products and to extend the adsorbent's useful life, adsorbents should generally be inert and not react with or catalyze reactions of adsorbate molecules. These considerations often affect adsorbent selection or require limits be placed upon the severity of operating conditions to minimize reactions of the adsorbate molecules or damage to the adsorbents.

Adsorbent Principles

Commercially useful adsorbents can be classified by the nature of their structure (amorphous or crystalline), by the sizes of their pores (micropores, mesopores, and macropores), by the nature of their surfaces (polar, nonpolar, or intermediate), or by their chemical composition. All of these characteristics are important in the selection of the best adsorbent for any particular application. However, the size of the pores is the most important initial consideration because if a molecule is to be adsorbed, it must not be larger than the pores of the adsorbent.

Not only do the more highly polar molecular sieve zeolites adsorb more water at lower pressures than do the moderately polar silica gels and alumina gels, but they also hold onto the water more strongly at higher temperatures. For the same reason, temperatures required for thermal regeneration of water-loaded zeolites are higher than for less highly polar adsorbents.

Physical properties of importance include particle size, density, volume fraction of intraparticle and extraparticle voids when packed into adsorbent beds, strength, attrition resistance, and dustiness. These properties can be varied intentionally to tailor adsorbents to specific applications. See also **Adsorption: Liquid Separation**; and **Molecular Sieve**.

Gradual adsorbent degradation by chemical attack or physical damage commonly occurs in many uses, accompanied by declining separation performance. Allowance for this must be taken into account in design of the process and in scheduling the replacement of spent adsorbents.

Adsorption Processes

Adsorption processes are often identified by their method of regeneration. Temperature-swing adsorption (TSA) and pressure-swing (PSA) are the

most frequently applied process cycles for gas separation. Purge-swing cycles and nonregenerative approaches are also applied to the separation of gases. Special applications exist in the nuclear industry. Others take advantage of reactive sorption. Most adsorption processes use fixed beds, but some use moving or fluidized beds.

Advances in fundamental knowledge of adsorption equilibrium and mass transfer will enable further optimization of the performance of existing adsorbent types. Continuing discoveries of new molecular sieve materials will also provide adsorbents with new combinations of useful properties. New adsorbents and adsorption process will be developed to provide needed improvements in pollution control, energy conservation, and the separation of high value chemicals. New process cycles and new hybrid processes linking adsorption with other unit operations will continue to be developed.

ADSORPTION: LIQUID SEPARATION. Liquid-phase adsorption has long been used for the removal of contaminants present at low concentrations in process streams. In most cases, the objective is to remove a specific feed component; alternatively, the contaminants are not well defined, and the objective is the improvement of feed quality defined by color, taste, odor, and storage stability.

In contrast to trace impurity removal, the use of adsorption for bulk separation in the liquid phase on a commercial scale is a relatively recent development.

An adsorbent can be visualized as a porous solid having certain characteristics. When the solid is immersed in a liquid mixture, the pores fill with liquid, which at equilibrium differs in composition from that of the liquid surrounding the particles. These compositions can then be related to each other by enrichment factors that are analogous to relative volatility in distillation. The adsorbent is selective for the component that is more concentrated in the pores than in the surrounding liquid.

A significant advantage of adsorbents over other separative agents lies in the fact that favorable equilibrium-phase relations can be developed for particular separations; adsorbents can be produced that are much more selective in their affinity for various substances than are any known solvents. This selectivity is particularly true of the synthetic crystalline zeolites containing exchangeable cations.

The search for a suitable adsorbent is generally the first step in the development of an adsorption process. A practical adsorbent has four primary requirements: selectivity, capacity, mass transfer rate, and long-term stability. The requirement for adequate adsorptive capacity restricts the choice of adsorbents to microporous solids with pore diameters ranging from a few tenths to a few tens of nanometers.

Traditional adsorbents such as silica, SiO_2; activated alumina, Al_2O_3; and activated carbon, C, exhibit large surface areas and micropore volumes. The surface chemical properties of these adsorbents make them potentially useful for separations by molecular class. However, the micropore size distribution is fairly broad for these materials. This characteristic makes them unsuitable for use in separations in which steric hindrance can potentially be exploited.

In contrast to these adsorbents, zeolites offer increased possibilities for exploiting molecular-level differences among adsorbates. Zeolites are crystalline aluminosilicates containing an assemblage of SiO_4 and AlO_4 tetrahedra joined together by oxygen atoms to form a microporous solid, which has a precise pore structure. Nearly 40 distinct framework structures have been identified to date. The versatility of zeolites lies in the fact that widely different adsorptive properties may be realized by the appropriate control of the framework structure, the silica-to-alumina ratio (Si/Al), and the cation form.

Commercial Processes

Industrial-scale adsorption processes can be classified as batch or continuous. In a batch process, the adsorbent bed is saturated and regenerated in a cyclic operation. In a continuous process, a countercurrent staged contact between the adsorbent and the feed and desorbent is established by either a true or a simulated recirculation of the adsorbent. The efficiency of an adsorption process is significantly higher in a continuous mode of operation than in a cyclic batch mode. For difficult separations, batch operation may require 25 times more adsorbent inventory and twice the desorbent circulation rate than does a continuous operation. In addition, in a batch mode, the four functions of adsorption, purification, desorption, and displacement of the desorbent from the adsorbent are inflexibly linked, whereas a continuous mode allows more degrees of freedom with respect to these functions, and thus a better overall operation.

The need for a continuous countercurrent process arises because the selectivity of available adsorbents in a number of commercially important separations is not high.

Since the 1960s the commercial development of continuous countercurrent processes has been almost entirely accomplished by using a flow scheme that simulates the continuous countercurrent flow of adsorbent and process liquid without the actual movement of the adsorbent. The idea of a simulated moving bed (SMB) can be traced back to the Shanks system for leaching soda ash.

Such a concept was originally used in a process developed and licensed by UOP under the name UOP Sorbex.

Continuous processes have wide application in different areas of the chemical industry. The separation efficiency of a continuous process is generally higher than that of a batch or cyclic-batch process. However, in some applications the cyclic-batch process may be preferred because of the complexity of design and the difficulty of controlling the continuous processes.

Conventional liquid chromatography has not attained great commercial significance in the area of large-scale bulk separations from the liquid phase. In analytical chromatography, the primary objective is to maximize the resolution between two components subject to some restrictions on the maximum time of elution. As a result, the feed pulse loading is minimized, and the number of theoretical plates is maximized. In preparative chromatography, the objective is to maximize production rate as well as reduce capital and operating costs at a given separation efficiency. The adsorption column is therefore commonly run under overload conditions with a finite feed pulse width. The choice of operating conditions for preparative chromatography has been discussed. In production chromatography, the optimal pulse sequence occurs when the successive pulses of feed are introduced at intervals such that the feed components are just resolved both within a given sample and between adjacent samples. See also **Liquid Chromatography**.

Outlook

Liquid adsorption processes hold a prominent position in several applications for the production of high purity chemicals on a commodity scale. Many of these processes were attractive when they were first introduced to the industry and continue to increase in value as improvements in adsorbents, desorbents, and process designs are made.

The value of many chemical products from pesticides to pharmaceuticals to high performance polymers, is based on unique properties of a particular isomer from which the product is ultimately derived. Often the purity requirement for the desired product includes an upper limit on the content of one or more of the other isomers. This separation problem is a complicated one, but one in which adsorptive separation processes offer the greatest chances for success.

ADSORPTION INDICATORS. Dyestuffs or other chemicals that are used to detect the end point of a precipitation titration. These substances are dissolved in the solution to be titrated and lend color to it. The end point of the titration is signaled by disappearance of the color from the

solution, or a change of color in the solution, attributable to adsorption of the indicator by the precipitate. See also **Indicator (Chemical)**.

ADSORPTION (Process). The *physical* property of certain materials to adsorb certain other substances is used widely in the chemical and petrochemical industries for purifying (removing undesirable components) various gases, such as *syngases*, that are the feedstock for synthesizing numerous organic chemicals (methanol, for example) and also fuel gases (natural or synthetic). As a major chemical engineering *separating technique*, adsorption sometimes competes with absorption, q.v., membrane, and membrane separation operations.

Definition. Adsorption is a type of adhesion that takes place at the surface of a solid or a liquid in contact with another medium, resulting in an accumulation or increased concentration of molecules from that medium in the immediate vicinity of the surface. For example, if freshly heated charcoal is placed in an enclosure with ordinary air, a condensation of certain gases occurs upon it, resulting in a reduction of pressure; or if it is placed in a solution of unrefined sugar, some of the impurities are likewise adsorbed, and thus removed from the solution. Charcoal, when activated (i.e., freed from adsorbed matter by heating), is especially effective in adsorption, probably because of the great surface area presented by its porous structure. See Fig. 1. Its use in gas masks is dependent upon this fact. Penicillin is recovered in one state of the process by adsorption on activated carbon.

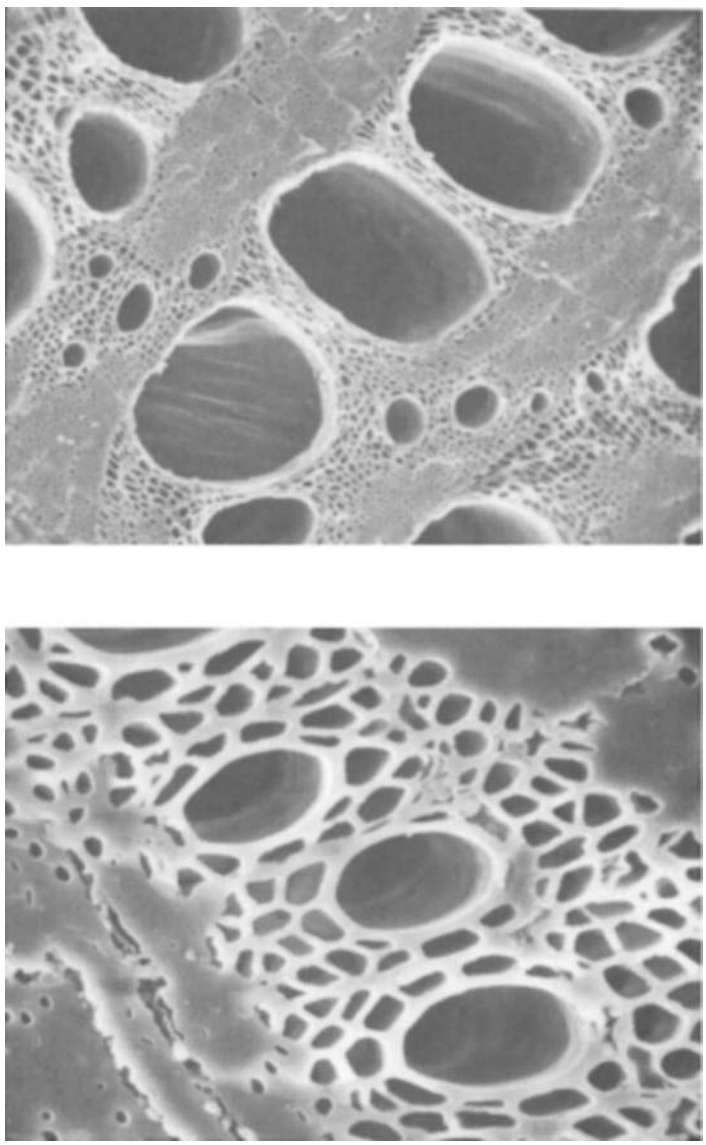

Fig. 1. Scanning electron micrographs of charcoal magnified 100× (top) and 50× (bottom). (*Polaroid Type 105 Land Film*.)

When colloidal hydroxides, notably aluminum hydroxide, are precipitated in a solution of acidic dyes, that is, those containing the groups −OH or −COOH, the dye adheres to the precipitate, yielding what is termed a lake. The "adsorption" of dirt on one's hands results from the unequal distribution of the dirt between the skin of the hands and the air or solid with which the skin comes in contact. Water is frequently ineffective in removing the dirt. The efficacy of soap in accomplishing its removal is due to the unequal distribution of dirt between skin and soap "solution," this time favoring the soap and leaving the hands clean.

At a given fixed temperature, there is a definite relation between the number of molecules adsorbed upon a surface and the pressure (if a gas) or the concentration (if a solution), which may be represented by an equation, or graphically by a curve called the *adsorption isotherm*.

The Freundlich or classical adsorption isotherm is of the form

$$\frac{x}{m} = kp^{1/n}$$

in which x is the mass of gas adsorbed, m is the mass of adsorbent, p is the gas pressure, and k and n are constants for the temperature and system. In certain systems, it is necessary to express this relationship as

$$\frac{x}{m} = k(h\gamma)^{1/n}$$

where h is the relationship of the partial pressure of the vapor to its saturation value, and γ is the surface tension. Numerous isotherm equations have been proposed in the chemical literature in the last fifty years. The Langmuir adsorption isotherm is of the form

$$\frac{x}{m} = \frac{k_1 k_2 p}{1 + k_1 p}$$

The Brunauer, Emmett and Teller equation is more general than those of Freundlich or Langmuir; for among other limitations, those two equations apply only to the adsorption of gases. Even in those cases, the degree of adsorption depends upon five factors: (1) the composition of the adsorbing material, (2) the condition of the surface of the adsorbing material, (3) the material to be adsorbed, (4) the temperature, and (5) the pressure (if a gas). A notable case in point is carbon. Of the finely divided varieties of carbon there are important sugar charcoal, bone black or animal black, blood charcoal, wood charcoal, coconut-shell charcoal, activated carbon. The temperature of preparation of adsorbent charcoal is an important factor, high temperatures being deleterious, and the removal (or non-removal) of gases by passing steam over the heated carbon, which operation increases the adsorptive power. Bone black is used for removing the coloring matter from raw sugar solutions. Fusel oil is removed from whiskey and poison gases from air by adsorption with the proper form of carbon. By cooling carbon in a vacuum to the temperature of liquid air, the concentration of residual gas is greatly decreased. Dewar (1906) found that 5 grams of charcoal (presumably coconut-shell charcoal) at the temperature of liquid air reduced the pressure of air in a 1-liter container from 1.7 to 0.00005 millimeters.

Major Adsorbents. Besides carbon, other important adsorbents are infusorial or diatomaceous earth fuller's earth, clay, activated silica (silica gel), activated alumina, and synthetic zeolites. See Table 1. All surfaces that behave indifferently towards non-electrolytes have the ability to adsorb electrolytes.

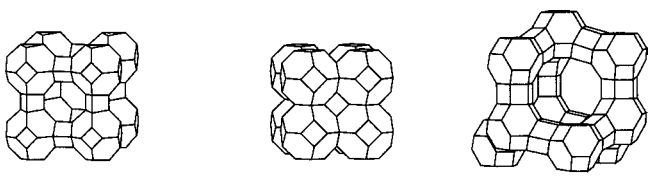
As pointed out by Ruthven, the discovery and commercialization of synthetic zeolites as adsorbents provided the primary stimulus to the development of adsorption as a major separation process. Although, more recently, other materials, such as organic resins, carbon molecular sieves, and pillared clays, have appeared, the zeolites remain a dominant factor in adsorbent selection. See Fig. 2. Because of their microporous crystalline structure, zeolites are uniquely suited to the role of adsorbents. Although commercially available only in recent years, it is interesting to note that R.M. Barrow first recognized the adsorbent selectivity potential of zeolites in the 1940s. Earlier research was directed towards natural zeolites. (Synthetic zeolites also are used in catalytic processes. See **Catalysis**.)

Classes of Adsorbents. On the basis of the adsorbate (or the substance which is adsorbed), adsorption may be *polar*, when the material adsorbed consists of positive or negative ions, so that the adsorbed film has an overall electrical charge. The term polar adsorption is also applied to adsorption chiefly attributable to attraction between polar groups of adsorbate and adsorbent. *Specific* adsorption is the preferential adsorption

TABLE 1. PHYSICAL PROPERTIES OF REPRESENTATIVE ADSORBENTS

Adsorbent Substance	Internal Porosity (%)	External Void Fraction (%)	Average Diameter (10^{-10} meter)	Surface Area (square meters/gram)	Adsorptive Capacity (gram/gram of dry solid)
Activated alumina	25	49	34	250	0.14[a]
Activated bauxite	35	40	∼50	—	0.04–0.2[b]
Fuller's earth	∼54	40	—	130–250	—
Silica gel	∼70	30–40	25–30	∼320	1.0[c]
Shell-base carbon	∼50	∼37	20	800–1100	45
Wood-base carbon	55–75	∼40	20–40	625–14,000	6–9[d]
Coal-base carbon	65–75	45–70	20–38	500–1200	∼0.4[e]
Petroleum-base carbon	70–85	26–34	18–22	800–1100	0.6–0.7[f]
Anhydrous calcium sulfate	38	45	—	—	0.1[g]
Synthetic zeolites — See Note below. —					

[a] Water at 60% relative humidity.
[b] Water; test condition not specified.
[c] Water at 100% relative humidity.
[d] Phenol value.
[e] Benzene at 20 °C; 7.5 millimeters partial pressure.
[f] Test conditions not specified.
[g] Water; test conditions not specified.
Note: Synthetic zeolites are available from numerous commercial sources and usually are best known by their tradenames.
Pore Size: Ranges from 3 Å (*Phillipsite*) to 6 × 7 Å for *Mordenite*.
Composition: Si/Al: 1.0 for *US-Y* to 5–10 for *Ferrierite* and *Mordenite*.
Cation: Na, H, K, Ca, and Mg varies with different formulations.
Sorption Capacity (Wt%): H_2O: 1 for *Silicalite* to 28 for *Faujasiite X*
nC_6H_{14}: 1.3 for *Phillipsite* to 18.1 for *Faujasite Y*
C_6H_{12}: 1 for *Chabazite* to 19.5 for *Faujasite Y*
Note that, for all the foregoing, there are numerous intermediate values.
Suppliers include: Anaconda Minerals, Double Eagle Mining, W.R. Grace, Mobil Oil, PQ Corp, Toyo Soda, Union Carbide, et al. Adapted from data developed by D.E.W. Vaughan.



(**a**) (**b**) (**c**)

Fig. 2. Three types of zeolites used in adsorption operations. (**a**) A type, (**b**) *Sodalite*, and (**c**) *Faujasite* (Type X, Y). Zeolites are crystalline microporous solids that contain cavities and channels measured in terms of molecular dimensions. Sometimes called *molecular sieves*, these dimensions range from 3 to 10 Å. At one time, zeolites were chemically classified as aluminosilicates. With the development of aluminophosphate chemistry, at least 13 additional elements have been added to their composition, including Li, Be, B, Mg, Co, Mn, Zn, P, As, and Ti, plus the earlier known substitution of Si, Al, Ga, Ge, and Fe. As pointed out by Vaughan, "Few fields of chemistry (inorganic) offer such chemical and structural diversity." There are 60 different known structures, but theorists suggest that tens of thousands may be possible. The foundation building block of zeolite structure is a tetrahedron of four oxygen atoms surrounding a central silicon atom (SiO_4). Natural zeolites also occur, q.v. (*Sketches adapted from Vaughan.*)

of one substance over another, or the quantity of adsorbate held per unit area of adsorbent.

On the basis of the process involved, adsorption may be classified as *chemical adsorption* (or chemisorption) where forces of chemical or valence nature between adsorbate and adsorbent are involved; and *Van der Waals adsorption*, involving chiefly Van der Waals forces. The difference is usually indicated experimentally by the greater heat of adsorption and more specific nature of the chemical process.

In comparing the adsorption properties of silica gel and activated carbon it may be noted that the latter is nonpolar and since it has no affinity for water will adsorb organic compounds in preference to water. Silica gel, on the other hand, is polar. It retains water and may thus reject an organic compound. It can also discriminate more selectively than activated carbon and consequently can be used for the fractionation of organic solvents.

Other types of adsorption are *oriented adsorption*, in which the adsorbed molecules or other entities are directionally arranged on the surface of the adsorbent; and *negative adsorption*, a phenomenon exhibited by certain solutions, in which the concentration of solute is less on the surface than in the body of the solution.

Occlusion. is a type of adsorption, or perhaps more properly absorption, exhibited by metals or other solids toward gases, in which the gas is apparently incorporated in the crystal structure of the solid. Palladium thus occludes extraordinary quantities of hydrogen, with the simultaneous liberation of much heat.

Applications and Equipment Required. Industrial adsorption processes are relatively complex and consist of several steps, as in the case of removing (adsorbing) undesirable vapors and gases from a mixture of gases: (1) passing the gas mixture through an adsorption column under pressure, (2) regeneration of the column through the application of heat and a purging gas, (3) cooling the column, and (4) repressurization of the column to make ready for the next cycle.

Adsorption is extremely important in biological reactions. Many of the constituents of plant and animal cells are colloidal in nature, and materials of various sorts are adsorbed on the surfaces of these colloids. For example, proteins frequently depend upon hydration or the adsorption of water for their activity, and the cellulose walls of plant cells often adsorb much water. See also **Chromatography**.

During recent years, large installations for processing municipal wastes have been made. By taking advantage of anaerobic (do not require oxygen to live) bacteria, close to 100% of the waste mass can be converted to large volumes of usable gas (methane), leaving relatively small amounts of dry solids. The gas produced is known as landfill gas (LFG). Wells are drilled into the landfill, with the application of a slight vacuum to avoid drawing air into the base of the fill. LFG contains a variety of non-biodegradible chemicals, including chlorinated fluorinated hydrocarbons, plus the remainders of hundreds of packaged chemicals (solvents, cleaners, et al.). The raw LFG also contains large quantities of carbon dioxide, which must be removed. Nearly all of the undesired components can be removed via selective adsorption. Usually, the target is to produce a medium-energy gas, for use as boiler fuel or in gas turbine electrical generators, or a high-energy, pipeline-quality methane stream.

In 1990, it was estimated that existing or proposed landfill plants would produce well over 100 million SCF (standard cubic foot), equivalent to nearly 3.5 billion cubic meters of raw LFG per year.

Adsorption plays an important role in the process of dyeing, and in contact catalytic processes such as the conversion of sulfur dioxide to trioxide, and of nitrogen plus hydrogen to ammonia. In the case

of insoluble organic acids (containing −COOH group) and substances containing hydroxyl (−OH) groups on the surface of water, the film is oriented so that the −COOH or −OH groups are attracted into the surface of the water, while their hydrocarbon ends project away from the surface of the water, showing no tendency to dissolve (Langmuir).

The heat of adsorption, or wetting in this case, of starch by water is 29 calories per gram of dry starch. The heat of adsorption of various vapors and adsorbents has been measured. Since increase of temperature reduces adsorption, the adsorption process is accompanied by the evolution of heat. It appears that the heat liberated for a given volume of liquid filling the capillary spaces of a given adsorbent is practically constant. The heat of adsorption of hydrogen is, on nickel, palladium, platinum, copper, 11,700, 18,000, 13,800, 9500 calories respectively per gram mol (2 grams) of hydrogen; and of carbon monoxide on platinum 35,000 calories per gram mol (28 grams) of carbon monoxide; and of ethylene on copper 9500 calories per gram mol (28 grams) of ethylene.

ADVANCED COMPOSITION EXPLORER (ACE). The ACE is an Explorer mission that was managed by the Office of Space Science Mission and Payload Development Division of the National Aeronautics and Space Administration (NASA). More on the ACE personnel, including scientific Co-Investigators can be found at http://www.srl.caltech.edu/ACE/ace personnel.html.

The Earth is constantly bombarded with a stream of accelerated particles arriving not only from the Sun, but also from interstellar and galactic sources. Study of these energetic particles or cosmic rays, contributes to our understanding of the formation and evolution of the solar system as well as the astrophysical processes involved. The Advanced Composition Explorer (ACE) spacecraft carries six high-resolution sensors and three monitoring instruments to sample low-energy particles of solar origin and high-energy galactic particles with a collecting power 10 to 1000 times greater than past or planned experiments.

From a vantage point approximately 1/100 of the distance from the Earth to the Sun ACE performs measurements over a wide range of energy and nuclear mass, under all solar wind flow conditions and during both large and small particle events including solar flares. ACE provides near-real-time solar wind information over short time periods. When reporting space weather, ACE can provide an advance warning (about one hour) of geomagnetic storms that can overload power grids, disrupt communications on Earth, and present a hazard to astronauts. See also **Solar Flares**; and **Solar Wind**.

The spacecraft is 1.6 meters (5.25 ft) across and 1 meter (3.28 ft) high, not including the four solar arrays and the magnetometer booms attached to two of the solar panels. See Fig. 1. At launch, it weighed 785 kg (1,731 lbs), which includes 189 kg (417 lbs) of hydrazine fuel for orbit insertion and maintenance. The solar arrays generate about 500 watts of power. The spacecraft spins at 5 rpm, with the spin axis generally pointed along the Earth-sun line and most of the scientific instruments on the top (sunward) deck.

Fig. 1. Advanced Composition Explorer spacecraft. (*image courtesy of NASA.*)

ACE was launched on a McDonnell−Douglas Delta II 7920 launch vehicle on August 25, 1997 from the Kennedy Space Center in Florida.

In order to get away from the effects of the Earth's magnetic field, the ACE spacecraft has traveled almost a million miles (1.5 million km) from the Earth to the Earth-sun libration point (L1). Figure 2 illustrates by orbiting the L1 point, ACE will stay in a relatively constant position with respect to the Earth as the Earth revolves around the sun.

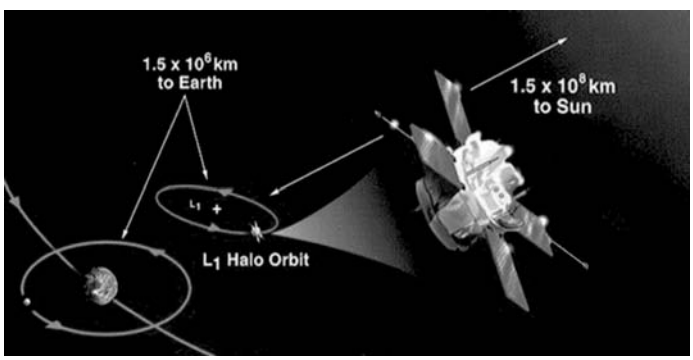

Fig. 2. ACE orbit. (*image courtesy of NASA.*)

Science Goals

The primary purpose of ACE is to determine and compare the isotopic and elemental composition of several distinct samples of matter, including the solar corona, the interplanetary medium, the local interstellar medium, and Galactic matter.

The nine scientific instruments on ACE are performing:

- **Comprehensive and coordinated composition determinations**
  - Elemental
  - Isotopic
  - Ionic charge state
- **Observations spanning broad dynamic range**
  - Solar wind to galactic cosmic ray energies (∼100 eV/nucleon to ∼500 MeV/nucleon)
  - Hydrogen to Zinc (Z = 1 to 30)
  - Solar active and solar quiet periods
- **Investigations of the origin and evolution of solar and galactic matter**
  - Elemental and isotopic composition of matter
  - Origin of the elements and subsequent evolutionary processing
  - Formation of the solar corona and acceleration of the solar wind
  - Particle acceleration and transport in nature

ACE Instruments

CRIS. The Cosmic Ray Isotope Spectrometer on the Advanced Composition Explorer (ACE) spacecraft is intended to be a major step in ascertaining the isotopic composition of the cosmic rays and hence a major step in determining their origin. The GCRs consist, by number, primarily

of hydrogen nuclei (~92%) and He nuclei (~7%). The heavier nuclei (1%) provide most of the information about cosmic-ray origin through their elemental and isotopic composition. The intensities of these heavy cosmic rays are very low and progress in the past has been impeded by limited particle collection power, particularly regarding individual isotopes. CRIS is designed to have far greater collection power (~250 cm^2-sr) than previous satellite instruments (<10 cm^2-sr) while still maintaining excellent isotopic resolution up through Z = 30 (Zinc) and beyond.

The elemental and isotopic composition of the Sun, which will be studied by SIS and other instruments on ACE, will provide one of the essential yardsticks by which to interpret the cosmic ray composition.

ULEIS. The Ultra Low Energy Isotope Spectrometer measures ion fluxes over the charge range from He through Ni from about 20 keV/nucleon to 10 MeV/nucleon, thus covering both suprathermal and energetic particle energy ranges. Exploratory measurements of ultra-heavy species (mass range above Ni) will also be performed in a more limited energy range near 0.5 MeV/nucleon. ULEIS will be studying the elemental and isotopic composition of solar energetic particles, and the mechanisms by which these particles are energized in the solar corona. ULEIS will also investigate mechanisms by which supersonic interplanetary shock waves energize ions.

SWIMS. The Solar Wind Ions Mass Spectrometer instrument on ACE is optimized for measurements of the chemical and isotopic composition of solar and interstellar matter. SWIMS is a time-of-flight mass spectrometer with an electrostatic analyzer. SWIMS measures the chemical and isotopic composition of the solar wind for every element between He and Ni, up to 10 keV/e.

EPAM. The Electron, Proton, and Alpha Monitor is composed of five telescope apertures of three different types. Two Low Energy Foil Spectrometers (LEFS) measure the flux and direction of electrons above 30 keV (geometry factor = 0.397 cm^2 sr), two Low Energy Magnetic Spectrometers (LEMS) measure the flux and direction of ions greater than 50 keV (geometry factor = 0.48 cm^2 sr), and the Composition Aperture (CA) measures the elemental composition of the ions (geometry factor = 0.24 cm^2 sr). The telescopes use the spin of the spacecraft to sweep the full sky. Solid-state detectors are used to measure the energy and composition of the incoming particles.

MAG. The Magnetometer instrument will measure the local interplanetary magnetic field (IMF) direction and magnitude and establish the large scale structure and fluctuation characteristics of the IMF at 1 AU upstream of Earth as a function of time throughout the mission. This experiment will provide: continuous data at 3,4 or 6 vectors/sec, and snapshot memory data and Fast Fourier Transform data (FFT) based on 24 vectors/sec. acquired on board, working synchronously with blocks of 512 samples (FFT only) each.

These measurements will be precise, accurate, and ultra sensitive. The basic instrument is a twin triaxial fluxgate magnetometer system. Each of two identical sensors is on booms that extend past the end of diametrically opposite solar panels. The digital processing unit utilizes a 12 bit A/D converter to easily resolve small amplitude fluctuations of the field, and is microprocessor controlled. It also incorporates a dedicated FFT processor developed around high performance DSP integrated circuits, which produces a 32 channel logarithmic spectrum for each axis, synthesized from a "raw" 256 point linear spectrum. All components of the power spectral matrices corresponding to the 32 estimates are transmitted to the ground once every 80 seconds, providing power and phase information together with the corresponding snapshot memory time series data. As in previous instruments developed at GSFC, high reliability is obtained by the use of fully redundant systems and extremely conservative designs. The intrinsic zero drift of the sensors is expected to be below 0.1 nT over periods of up to 6 months. Electrical "flippers" designed to simulate a 180 degree mechanical rotation of the sensors, will be used to monitor the zero level drift associated with aging of electronic components. The use of advanced statistical techniques for estimating absolute zero levels is also planned. The instruments feature a very wide dynamic range of measurements capability, from ± 4 nT up to ± 65,536 nT per axis in eight discrete ranges; all ranges can be activated either by command or, most commonly, automatically. The upper range permits end to end testing in the Earth's magnetic field without the need for special field cancellation coils or magnetic shields.

SIS. The Solar Isotope Spectrometer is designed to provide high resolution measurements of the isotopic composition of energetic nuclei from He to Ni (Z = 2 to 28) over the energy range from ~10 to ~100 MeV/nucleon. During large solar events, when particle fluxes can increase over quiet-time values by factors of up to 10000, SIS will measure the isotopic composition of the solar corona, while during solar quiet times SIS will measure the isotopes of low-energy Galactic cosmic rays and the composition of the anomalous cosmic rays which are thought to originate in the nearby interstellar medium. The solar energetic particle measurements are useful to further our understanding of the Sun, while also providing a baseline for comparison with the Galactic cosmic ray measurements carried out by CRIS.

SIS has a geometry factor of ~40 cm^2-sr, which is significantly larger than previous satellite solar particle isotope spectrometers. It is also designed to provide excellent mass resolution during the extremely high particle flux conditions which occur during large solar particle events.

SIS is also part of the Real Time Solar Wind (RTSW) set of instruments flying aboard ACE. Four of ACE's nine instruments will be constantly monitored by the National Oceanic and Atmospheric Administration (NOAA) operated ground stations. The data from these instruments will be used by NOAA to evaluate the risk of geomagnetic storms from solar events and to make predictions of these storms rapidly available.

SEPICA. The Solar Energetic Particle Ionic Charge Analyzer was built as a collaboration between the UNH Space Science Group and the National Aeronautics and Space Administration (NASA). Its mission is to collect information about particles emanating from the Sun. SEPICA detects the ionic charge state, kinetic energy, and nuclear charge of ions coming from the Sun, and with that information, one can determine not only the type of ions present, but also the history of those ions within the Sun. This aids scientists in their understanding of the Sun and the processes that take place within it.

SWEPAM. The Solar Wind Electron, Proton, and Alpha Monitor measures the solar wind plasma electron and ion fluxes (rates of particle flow) as functions of direction and energy. These data provide detailed knowledge of the solar wind conditions and internal state every minute. SWEPAM also provides real-time solar wind observations which are continuously telemetered to the ground for space weather purposes.

Electron and ion measurements are made with separate sensors. The ion sensor measures particle energies between about 0.26 and 36 KeV, and the electron sensor's energy range is between 1 and 1350 eV. Both sensors use electrostatic analyzers with fan-shaped fields-of-view. The electrostatic analyzers measure the energy per charge of each particle by bending their flight paths through the system. The fields-of-view are swept across all solar wind directions by the rotation of the spacecraft.

SWEPAM was built jointly by the Los Alamos and Sandia National Laboratories in New Mexico. It is built from the spare solar wind electron and ion analyzers from the Ulysses mission with selective modifications and improvements.

RTSW. The Real-Time Solar Wind Data, http://www.sec.noaa.gov/ace/, from NOAA's Space Environment Center (SEC), http://www.sec.noaa.gov/, provides up to an hour's advance warning of unusual solar activity, such as solar flares and coronal mass ejections, which can cause geomagnetic storms.

Four ACE instruments supply data to NOAA's SEC for RTSW processing. The instruments are: EPAM — Energetic Ions and Electrons; MAG — Magnetic Field Vectors; SIS — High Energy Particle Fluxes; and SWEPAM — Solar Wind Ions.

SWICS. The Solar Wind Ion Composition Spectrometer is optimized for measurements of the chemical and isotopic composition of solar and interstellar matter. SWICS is a time-of-flight mass spectrometer with an electrostatic analyzer. SWICS determines the chemical and ionic charge state composition of the solar wind and resolves H and He isotopes of both solar and interstellar sources. SWICS also measures the distribution functions of both the interstellar cloud and dust cloud pickup ions up to energies of 100 keV/e.

ADVECTION. The process of transport of an atmospheric property solely by the mass motion (velocity field) of the atmosphere; also, the rate of change of the value of the advected property at a given point.

Advection may be expressed in vector notation by

$$-\mathbf{u} \cdot \nabla\phi,$$

where **u** is the wind vector, φ the atmospheric property, and $\nabla\varphi$ the gradient of the property. In three-dimensional Cartesian coordinates, it is

$$-\left(u\frac{\partial\phi}{\partial x} + v\frac{\partial\phi}{\partial y} + w\frac{\partial\phi}{\partial z}\right),$$

where *u*, *v*, and *w* are the wind components in the eastward, northward, and vertically upward directions, respectively. The first two terms compose the horizontal advection and the last term is the vertical advection. Also, it should be noted that the property φ may itself be a vector field. Often, particularly in synoptic meteorology, advection refers only to the horizontal or isobaric components of motion, that is, the wind field as shown on a synoptic chart. Regarding the general distinction (in meteorology) between advection and convection, the former describes the predominantly horizontal, large-scale motions of the atmosphere, while convection describes the predominantly vertical, locally induced motions. In oceanography, advection refers to the horizontal or vertical flow of seawater as a current.

ADVECTION FOGS. See **Fog and Fog Clearing**.

ADVECTIVE CHANGE OF TEMPERATURE. See **Meteorology**.

ADVENTITIOUS BUDS. Buds which appear elsewhere than in the leaf axils or above them. They may appear anywhere in the internode, or on roots or even on leaves, and develop either naturally or as a result of injury. The dense bunches of buds, which frequently appear on burls or in witches'-broom, may be adventitious. The buds that appear at the tops of thistle roots, particularly when the natural top of the plant is cut off, are adventitious. So also are the buds that develop on the leaves of the begonia and bryophyllum. The practice of pollarding, or cutting off the branches of a tree in such a way as to leave only the main trunk or perhaps the stumps of a few large branches, results in the development of dense groups of adventitious buds. These grow into adventitious branches that in certain willows may be long and supple and so useful in manufacturing wicker furniture. The habit of forming adventitious buds on roots is of material value, since in consequence it is possible to propagate many plants by means of root cuttings.

Adventitious roots also exist. They may appear from the stem where they arise in the pericycle, or from other tissues of the plant. The roots that appear on slips or stem cuttings are adventitious. See also **Bud**; and **Budding**.

ADVISORY. See **Meteorology**.

AEOLIAN TONES. Sound, usually in the band of audible frequencies, associated with wake-eddy, vortex- produced pressure fluctuations resulting from air flow around obstacles, such as wires and twigs.

Although many such sounds are irregular noises, other familiar sounds involve fairly clear musical notes or humming sounds. The latter sounds were called aeolian tones by Rayleigh. Their pitch is controlled by the frequency with which eddies are formed and detached in the wake region on the lee side of the obstacle. The tones produced by wind flowing over a cylinder, including stretched wire, were shown by Strouhal in 1878 to be of frequency (pitch) *f* given by

$$f = 0.185\ u/d,$$

where *u* is the cross-axis wind velocity (m s^{-1}) and *d* is the cylinder diameter (m).

AMS

AERATION. A process of contacting a liquid with air, often for the purpose of releasing other dissolved gases, or for increasing the quantity of oxygen dissolved in the liquid. Aeration is commonly used to remove obnoxious odors or disagreeable tastes from raw water. The principle of aeration is also used in the treatment of sewage by a method known as the activated sludge process. The sewage is allowed to flow into an aeration tank where it is mixed with a predetermined volume of sludge. Compressed air is introduced which agitates the mixture and furnishes oxygen that is necessary for certain biological changes. Sewage may also be aerated by mechanically actuated paddles that rotate the liquid and constantly bring a fresh surface in contact with the atmosphere.

Aeration is of importance in the fermentation industries. In the manufacture of baker's yeast, penicillin, and other antibiotics, an adequate air supply is required for optimum yields in certain submerged fermentation processes.

Aeration can be accomplished by allowing the liquid to fall in a thin film or to be sprayed in the form of droplets in air at atmospheric pressure; or the air, under pressure, may be bubbled into the liquid by means of a sparger, or other device that creates thousands of small bubbles, thus providing maximum contact area between the air and the liquid.

AERENCHYMA. Spongy tissue occurring chiefly in the stems of many aquatic or marsh plants. Such porous tissue gives great buoyancy to the stem and so helps keep the leaves up in the air and permits gas diffusion within the plant. The term aerenchyma is frequently applied to any loose porous tissue found in plants, as for example that occurring in lenticels.

AEROBE. An organism that utilizes atmospheric oxygen in its metabolic processes; i.e., the so-called aerobic bacteria, or aerobes, which use oxygen. See also **Anaerobe**.

AEROBIC DIGESTION. See **Biosolids**.

AEROBIOLOGY. The study of the distribution of living organisms freely suspended in the atmosphere and some consequences of this distribution. It includes microorganisms and some insects, seeds, and spores. Dispersion is by the wind, aided in some species by special adaptations and in some by flight. Small organisms are lifted and maintained in the air by eddy diffusion and rising thermal currents, sometimes reaching heights exceeding 16 km (10 miles) in air currents and by lateral mixing. They may be collected by adhesive-coated slides exposed horizontally, or by culture media, but for quantitative work, volumetric sampling at the surface or by aircraft is required.

AERODUCT. A ramjet type of engine designed to scoop up ions and electrons freely available in the outer reaches of the atmosphere or in the atmospheres of other spatial bodies, and by a metachemical process within the duct of this engine, expel particles derived from the ions and electrons as a propulsive jetstream.

AERODYNAMICS AND AEROSTATICS. *Aerodynamics* is the study of the *interaction between* (1) a *fluid*, most frequently air, that is stationary or in motion (wind), and (2) a *solid object* that (a) is essentially *stationary* (fixed), such as a building, chimney, bridge, or that (b) is in *motion*, such as an airborne or land-borne vehicle, a missile, a sporting object (ball, boomerang), et al. This interaction, when translated to practical engineering terms, is of great importance in terms of designing structures and vehicles for maximum safety, performance, and efficiency. For example, in terms of fixed structures, a bridge must be designed to minimize the effects of high wind — to avoid undue swaying and possibly toppling under extreme conditions. (Bridges have been destroyed — e.g., the Tacoma Narrows Bridge, Washington, 1940.) For safety and other reasons, high rise buildings must be designed to minimize the effects

of wind. Aerodynamics is probably most commonly associated with the design of all types of aircraft, but much attention is also given to land craft, such as automobiles, trucks, and even bicycles. The interest in drag, discussed later, as it affects land vehicles has been intensified since the energy crisis of a few years ago — because a significant consumption of fuel is consumed in overcoming drag. The aerodynamic characteristics of vehicles also affect performance (the smoothness and grace of operation) as well as efficiency; also safety, particularly at high speeds, can be affected by aerodynamically designing an auto or truck that "holds the road" so to speak. Aerodynamics is or should be a major consideration in the design of trailing vehicles so that they can be operated safely under windy conditions. More recently, the disciplines of aerodynamics and acoustics have been combined to tackle "wind noise" in passenger cars. See **Acoustics**. The first streamlined train appeared in the 1930s (the so-called zephyrs) and aerodynamics was of major concern in the design of today's fastest trains, such as those operating in France and Japan. *Streamlining* is a general lay term for designing vehicles that incorporate sound aerodynamic engineering and that, aesthetically, appear to be so designed. There have been cases in the past where a so-called streamlined "look" was effected much more for buyer appeal than for the achievement of aerodynamic performance.

Aerodynamics is a complex, essentially mathematical and geometric science, but also one that has learned much from nature, rediscovering as it were the streamlining of birds, insects, and fast-moving land mammals. Aerodynamics depends upon the results of massive data collection, ranging from model testing (sometimes in huge wind tunnels) to test piloting aircraft and road testing of land vehicles. As will be touched upon later, computer simulation has aided and, in some cases, replaced the need for costly wind tunnel procedures.

Aerostatics. The basic principle of aerostatics can be attributed to Archimedes — a body immersed in a fluid (liquid or gas) is buoyed up by a force equal to the weight of the fluid displaced. Thus, for buoyancy, the weight of a structure (balloon, dirigible, etc.) plus the weight of the contained gas must equal the weight of the air displaced.

Fundamentals of Aerodynamics

Concept of Inversion. Whether an object is standing still and the air around it is in motion, or whether an object is moving in still air, provided the velocity of the object in the one case is the same as the velocity of the air in the other case, the prevailing aerodynamic forces are the same. This concept of inversion is exploited when determining the aerodynamic forces created by air streams upon stationary airfoils and other objects as they may be tested in the moving air streams of a wind tunnel. More simply stated, the wind detected by a person standing in a boat that is moving at 10 miles per hour, aerodynamically speaking, is the same as the wind felt by a person standing in a fixed position with a wind of 10 mph blowing.

Properties of Air. Air has a viscosity of 0.00019 poise under standard conditions, compared with 0.01 poise for water and 1 poise for light oil. Thus, there are fields of aerodynamic study in which the air can be considered frictionless, especially in subsonic aerodynamics — with the exception of the conditions existing in a very thin layer immediately adjacent to the solid object where there is relative motion between the object and the air. However, at speeds greater than that of sound, friction effects become important. In aerodynamic expressions, the absolute viscosity, μ, usually is associated with mass density, ρ as a ratio. This is called the *kinematic viscosity*, v, which has a magnitude of 0.000157 ft^2 (0.0000146 m^2) per second in standard sea level atmosphere.

At subsonic air speeds, it is customary to consider the air incompressible, and to rely on Bernoulli's theorem of the interchangeability of static head and velocity head. This permits the employment of the principle of continuity for flow, represented by the equation

$$AV = \text{constant}$$

which means, symbolically, that the product of the cross-sectional area of flow and the velocity is a constant at all points in the path taken by a finite quantity of the fluid. If the fluid were compressible, this continuity would be

$$\rho AV = \text{constant}$$

Streamtube. A streamtube in air may be visualized as an imaginary conduit through which the condition of continuity of flow of the incompressible fluid takes place. Although the flow is steady, the tube is not necessarily of uniform size, but where its sectional area decreases, we would anticipate an increase of velocity; furthermore, a consideration of Bernoulli's theorem would indicate that these diminished sections of the streamtube are regions of lower static pressure than elsewhere. Although a streamtube is ordinarily imagined to have a circular cross section, it will be convenient here to think of a streamtube having a rectangular cross section. If we have enough of these streamtubes, all of the same width, but whose heights may vary as velocity varies, we might imagine them stacked, one on another, as shown in Fig. 1, and be thus encompassing the whole flow of air through a given region. It will be convenient to think of the edges of these streamtubes as equivalent to the streamline pattern that is so useful in the study of the effect of airflows past solid objects. It follows that where the streamlines approach each other, there is a region of lower pressure and higher velocity; conversely when they diverge. Thus, converging streamtubes (and streamlines) are like nozzles, whereas diverging streamtubes are like diffusers. The reader, upon viewing a streamline pattern, may then judge fluid pressure by the density of streamlines. This is readily done, qualitatively, if not quantitatively.

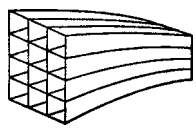

Fig. 1. Stacked streamtubes.

Streamline Patterns. It is now in order to state the nature of elementary streamline patterns and explain how a complex streamline pattern may be considered the result of the addition of two potential forces, each capable of producing a different character of streamline in the same region. A simple potential cylinder rotating in still air will drag with it a circulatory pattern of flow, the streamlines of which could be represented by a series of concentric circles. The circulation stream pattern is of great importance, because an airfoil is a shape that automatically induces a circulating component of airflow, which, when superimposed upon a rectilinear stream, provides the typical streamline pattern around an airfoil. The lifting streamline pattern of the typical airfoil could be induced in the absence of the airfoil by imposing some specific circulatory pattern of stream flow upon a rectilinear field, and this fact has been put to useful service in theoretical mathematical consideration of the aerodynamics of airfoils.

In Fig. 2a, a rectilinear flow is passing a static cylinder. At some distance from the cylinder, the flow is unaffected by the presence of the cylinder, and the streamtubes remain of constant size throughout, but it is obvious that between this undisturbed region and the cylinder, the intermediate tubes must be smaller in order that all can be accommodated in the space immediately above and below the cylinder. The action of the individual streamtube approaching a point abreast of the center line of the cylinder is, therefore, that of a nozzle which has increased the air speed and decreased its pressure. Hence, above and below the cylinder, static pressure is less than in the free, unaffected stream. If the cylinder were in rotation, tending to set up its concentric field of streamlines, the resulting streamline pattern would be like that shown in Fig. 2b, where, on one side of the cylinder, there is a reduction of static pressure due to crowding together of the streamlines, and on the other side, there may be no change of pressure, or even an increase. Briefly, then, the presence of a circulatory component of flow in a rectilinear field is to produce a net transverse force (in this case, upwards) on the object, since it will be subjected to unbalanced static pressure of the fluid against its surfaces. This is the force which causes a spinning tennis ball to assume a sharply curved trajectory, and which causes the lift to exist upon an airplane wing.

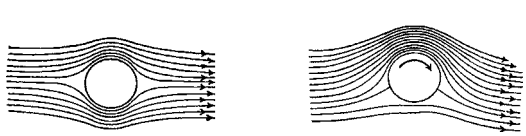

Fig. 2. Comparison of air passing over (**a**) cylinder at rest and (**b**) rotating cylinder.

Effects of Viscosity. The influence of viscosity of air in aerodynamics is confined chiefly to the action of air in the boundary layer. Within this boundary layer (which, although extremely thin, constitutes the atmosphere immediately adjacent to the solid) the frictional qualities of air are of importance in determining the airflow. The thin boundary layer might be imagined subdivided into a great many laminae of air parallel to the surface and extending out to the limits of the boundary layer. A non-turbulent boundary layer is considered, although, as will be developed later, the boundary layer may become turbulent under certain conditions except for the lamina immediately adjacent to the stationary surface. As Fig. 3 displays, the laminar velocity, u, increases above the surface until, at the edge of the boundary layer, it equals the free stream velocity. The smaller the viscosity of the fluid, the thinner the boundary layer will be. Consequently, it is extremely thin for air, but what goes on in this boundary layer is of utmost importance in aerodynamics. The first layer of air sticks or adheres to the surface, and laminae above it successively slide on each other, exerting drags that are proportional to the viscosity. The rate of change of the velocity between adjacent laminae is a measure of the unit shearing force between them, and is the unit skin friction when the lamina considered is at the one in motion nearest the stationary surface. This occurs at practically zero boundary layer thickness. A curve joining the tips of velocity vectors plotted for the different laminae in the boundary layer is called a velocity profile. If u is the variable velocity, increasing from 0 to V across the boundary layer, then du/dy is the rate of change of velocity (also the tangent to the velocity profile) and, through the application of one of the Newtonian principles, the unit shear stress,

$$\tau = \mu \left(\frac{du}{dy} \right)_{y=0}$$

where y is measured in the vertical direction.

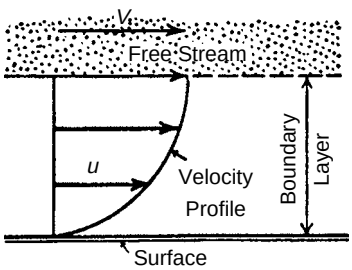

Fig. 3. Velocity profile.

Surface Effects. The proximity of streamlines to a stationary surface is now seen to produce a reaction resulting from the static pressure p existing in the flow nearest the surface, and a skin friction τ, which is, of course, tangential to the surface. The combination of these two is a force oblique to the surface. The foregoing statement premises an adherence of the streamlines to the surface, for, if they have separated from the surface, the region between will be filled with vortices of random motion, and the surface pressure cannot be definitely predicted from the character of the streamline flow. It is apparent that aerodynamic reaction is a function of μ, ρ, V, and the extent of the surface area on which the reaction takes place. Usually some one dimension l is taken to describe the size of the surface. In ft-lb sec units, the aerodynamic force F is in pounds, μ is in poises, ρ is in slugs per square foot, and l is in feet. To discover the relationship existing between the reaction and its controlling factors, it is customary to set up the dimensional relationship:

$$|F| = |\rho^a \mu^b V^c l^d|$$

and employ the methods of dimensional analysis to discover the value of a, b, c, and d. It is found that

$$|F| = \left| \left(\frac{v}{Vl} \right)^b \rho V^2 l^2 \right| \text{ dimensionally}$$

and

$$F = K \left(\frac{v}{Vl} \right)^b \rho V^2 l^2 \text{ numerically}$$

in which

v = kinematic viscosity
K = a dimensional constant
Vl/v = the Reynolds number (also dimensional)

The product $2K(v/Vl)^b\ b$, is frequently given as a dimensionless coefficient C. The exponent b is of such magnitude that the Reynolds number has a minor (but not negligible) effect on C. The coefficient is affected primarily by the attitude of the body in the airstream. If it is completely symmetrical, as is a sphere, this variation is nonexistent, and C is a true constant except for the above-mentioned minor effect of the Reynolds number variation. However, the nonsymmetrical shape of an airfoil causes large and typical variations of C, depending on the attitude with which the airfoil is presented to the airstream. The force F would then be $C(\rho V^2/2)S$, or CqS, in which q is dynamic pressure, and S is some significant surface area, in square feet, of the object.

Laminar and Turbulent Flow. Flow within a streamtube may be laminar or slightly turbulent. It was stated that, in laminar flow, drag per unit area is $\mu(\partial u/\partial y)_{y=0}$, but turbulent flow produces higher skin friction because the velocity profile is fuller close to the surface due to turbulent energy interchange between laminae. Although at the beginning of contact between airstream and surface, true laminar flow existed, it has been found that a certain critical value of Reynolds number, determined chiefly by the linear dimension of contact passed over, the boundary layer suddenly becomes turbulent, and thickens. In spite of the higher skin friction, the drag on bluff bodies may actually become less with turbulence, because of an action within the turbulent boundary layer that resists separation of the streamlines from the surface. Viscous drag gradually slows down the fluid in a laminar boundary layer, and if contact with the surface is maintained over sufficient length, the innermost parts of the boundary layer will be brought to rest. This becomes the separation point. If a negative pressure gradient exists beyond the separation point, as it often does, there will be a reverse flow toward the separation point, all of which will produce a breaking away of the streamlines from the surface, leaving the surface between the two separation points, on either side of body, in contact with air of random vortices and low pressure. See Figs. 4 and 5. It can be seen that because of the vortices, the pressure at n has failed to build up to the pressure at m (as it would have had the fluid been frictionless and without premature separation point), resulting in the creation of a downstream dragging force. This is characteristic of any body having a turbulent wake. Early turbulence in the boundary layer is desirable, so that the greater average momentum of boundary layer air can carry it against skin friction farther around the bluff surface, and so delay the separation point and narrow the turbulent wake. Thus, the coefficient of drag for a sphere [C of $Cq(\pi d^2/4)$] is about 0.5 for laminar boundary layer and 0.1 for turbulent, with the transition occurring at a Reynolds number of approximately 300,000.

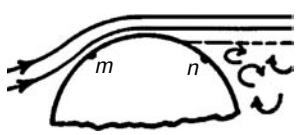

Fig. 4. Low-pressure wake.

Airfoils

An airfoil is any body whose shape causes it to receive a useful reaction from an airstream moving relative to it. This definition is broad and could include many shapes not ordinarily considered airfoils. The term is usually associated with a body of the shape shown in Fig. 6, a profile or chordwise section of the wing. The dimension perpendicular to this section is called the span when referred to the wing. Many different airfoil shapes have been used, proposed for use, or tested. Some of them have flat lower surfaces, and others have convex or concave surfaces.

The characteristic lifting airfoil profile has a maximum thickness of 6 to 18% of the chord at 20 to 40% of the chord aft of the leading edge. Early experiments were made with flat-plate airfoils, and later with thin curved-plate airfoils, but neither possessed as large a ratio of lift to drag at a particular angle of attack as the double-surface cambered airfoil shown, nor as low resistance or drag. Also, an airfoil of finite thickness provides space for the foundation structure of a lightweight wing, thus removing the

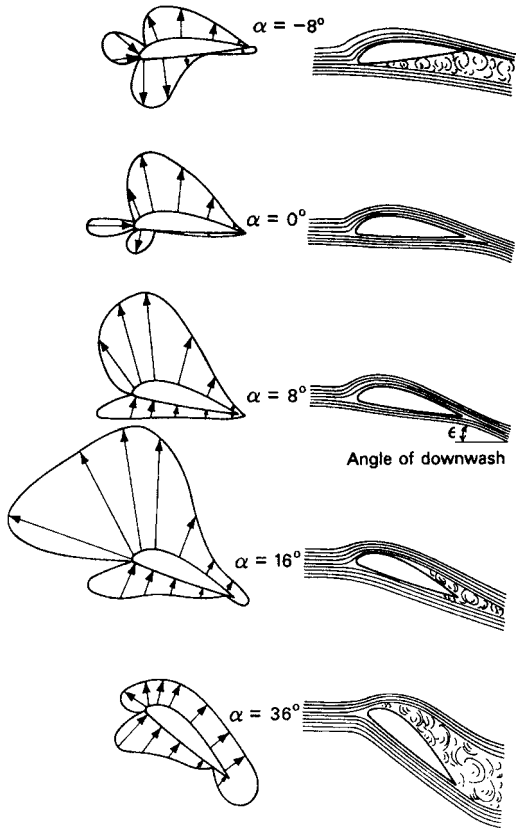

Fig. 5. Distribution of pressure on a cambered wing at different angles of attack but at the same airspeed as obtained in a wind tunnel. The arrows are force vectors, their length representing the relative intensities of the pressures at the points at which they are located. The end points (arrowheads) are connected to form an envelope. To obtain the relative intensity at any point, erect an arrow normal to the airfoil surface, and its length is then determined by its intersection with the envelope drawn through the end points of the other force vectors. Sketches to the right show, approximately, the manner of air flow at the different angles of attack.

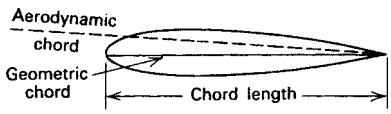

Fig. 6. Airfoil profile.

structural elements from the drag of the airstream, and thereby reducing the drag.

The value of the airfoil shape to aviation resides in the magnitude and direction of the resultant air reaction on it when employed at attitudes below the stall (about 15° angle of attack). The component of the air reaction normal (called the *lift*) to the free airstream is several times the magnitude of the parallel component (called the *drag*). The normal component, or lift, may be expressed in equation form as

$$L = C_L q S$$

The variation of C_L with geometric angle of attack is seen in Fig. 7. The slope of the straight portion is a per radian. Theory indicates a value of 2π for a, for infinite aspect ratio, and tests agree well with the theory. The lift coefficient increases uniformly with attack until the stall or burble point is reached, where it breaks and decreases rapidly with further increase of angle of attack, because the high attack angle creates a bluff body and the stagnation point advances forward on the airfoil. Normal controlled flight is not likely beyond the stall or burble point. The moment coefficient, C_{M_a}, about the aerodynamic center of the airfoil is shown in Fig. 7. It will be noted that it has practically a constant value. When listed, the value of C_{M_a}, at $C_L = 0$ is usually given.

The full aerodynamic reaction upon an airfoil is a force of which the lift is the component normal to the free stream velocity. The other component

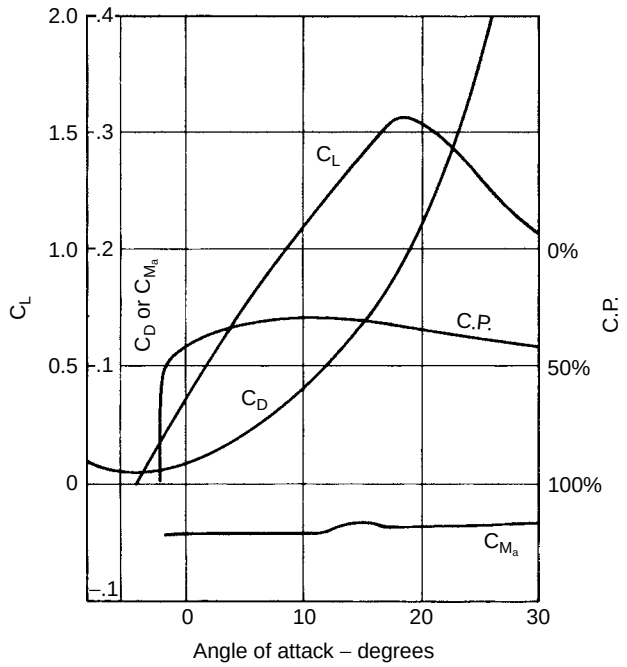

Fig. 7. Common aerodynamic characteristics of an airfoil.

is measured in the direction of the air velocity and is called drag. Drag coefficient has a characteristic parabolic variation, as Fig. 7 shows. The drag equation is analogous to that for the lift:

$$D = C_D q S$$

If the resultant of all air reactions on an airfoil is consolidated into a single imaginary force, it must act at the center of pressure of the airfoil. The figure shows that the location of this center of pressure of an airfoil varies with its attitude. The qualities of an airfoil that are sought for when employed in aviation are:

(1) High maximum C_L, in order to give low landing speed for a given size wing and weight.

(2) Low minimum C_D, so that the high speed, which occurs at small angles of attack, may be the greatest possible.

(3) High ratio of C_L to C_D, so that an efficient, economical airplane will result.

(4) A shape well suited to the construction of a strong, but lightweight, wing, at minimum cost.

Downwash. From an airfoil of finite span in flight, there is a multitude of vortices trailing, forming a vortex sheet. As a result of circulatory flow about each vortex filament a net downwash flow of air is produced, having an important effect upon the air reactions. If the airfoil is untwisted, and elliptical in plan form (or tapered in approximation of an ellipse), the vortices bound to the airfoil will produce a circulation of approximately elliptical strength distribution over the span. This produces a uniform downwash of air in the region of the wing. The combined effect of the forward motion of the airfoil and the downwash will be better understood upon reference to Fig. 8.

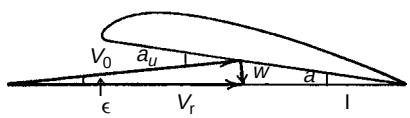

Fig. 8. Downwash.

The forward speed V_o and the vortex-induced downwash w produce a resultant air velocity of V_r (substantially equal to V_o in magnitude) which meets the airfoil at angle of attack α. The angle ϵ is called the downwash angle. Without downwash, the lift produced would be that corresponding to α_o at velocity V_o, but downwash reduces the angle of attack to α

thus decreasing the lift. To lift the same this airfoil would require α with downwash to be larger than α_o without downwash. The effect of downwash is now seen to be deleterious since, for the same V and lift, it increases the needed a and produces extra drag. Furthermore this drag (induced drag) is not associated with aerodynamic cleanliness but with aspect ratio. Disposing the area of the wing as a slender wing of large wing span (i.e., high aspect ratio) is the way to reduce this form of drag.

The effect of downwash of the wing has to be accounted for in the disposition of the empennage (stabilizing tail assembly) when disposed in the rear of the wing. In front of the wing, there is an upwash.

High-Lift Devices. The lifting ability of an airfoil is improved by increasing its camber (over limited range), and also by delaying the separation of the air flow from the lifting surface as the angle of attack is increased. Most airfoils employed as airplane wings are of low camber because their drag coefficients at low attack angles (high speed) are more favorable than those of the thick, highly cambered airfoils.

It is known that the maximum lift coefficient of a highly cambered airfoil is greater than that of a flat, thin one. Safety in landing an airplane demands low landing speed, which is obtainable by using wings with high maximum lift coefficients. On the other hand, high maximum speed is only to be obtained with the thin, low-drag type airfoil. Many manufacturers of aircraft have adopted the flap as a means for securing low landing speeds on aircraft fitted with inherently high-speed wings. The flap, as illustrated in Fig. 9, is akin to a flexible trailing edge, and, by depressing the flap, the effective camber of the airfoil may be increased. The drag is also increased, giving a steeper gliding angle with flap down than without the use of the flap. Apart from any disadvantage, this factor may actually be beneficial, since with flap position variable and under control of the pilot, the angle of normal gliding is alterable, permitting steep approaches to small, obstructed fields. Flaps that have received a great deal of attention include the simple flap, the split flap, zap flap, and the fowler flap. The simple flap, of which the normal aileron, elevator and rudder are types, is the easiest to use, requiring only rotation downward for increasing the lift coefficient. The split flap is extensively used. The operation is simply that of a rotation of a panel on the underside of the trailing edge about its forward edge. In the zap flap, the rotation is accompanied by a backward movement of the pivoting point. In the fowler flap, the motion is not one of simple rotation alone, but is combined with a rearward movement of the flap area as well. The effect is one of increase of airfoil area as well as change of camber.

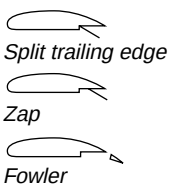

Fig. 9. Types of flaps.

Increasing lift by delaying separation in the boundary layer is an independent action. Both flaps and partial boundary layer control with the aid of a leading edge slot (see Fig. 10) could be added to the same airfoil — and have been on some airplane wings. The effect of flaps and slots on lift and drag is illustrated in Fig. 11. Delay of airflow separation by sucking off the incipient vortices around the stagnation point produced amazing lift coefficients but has not been exploited on account of the compressor energy needed, although, with the introduction of the jet engine, the interest in boundary layer control was revived. Also, very small high-speed jets to impart energy to the boundary layer, "blowing off" the

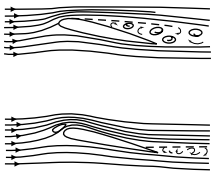

Fig. 10. Air flow at high angle of attack with and without slot.

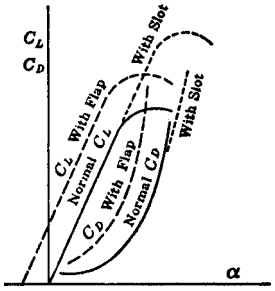

Fig. 11. Effect of flaps and slots on lift and drag.

air (as opposed to sucking off), and rotating cylindrical nose sections, have been tested with varying results.

Boundary layer control by leading edge slots is definitely valuable for lifting airfoils, and lacks the structural and mechanical complications attending the other boundary layer control proposals. Hence slots and flaps have been the principal high-lift additions commercially employed.

Drag

An object subjected to an airstream is acted upon by a resultant air pressure. Drag is the component of air reaction that is parallel to the airstream. Its origin is the profile impact of molecules of air against the face of the object, the skin friction of the molecules of air as they slide along the object, the vortices and eddying air currents set up in an otherwise undisturbed airstream by the presence of the object, and the induction effects of downwash, if any. Drag is that quantity which imposes limitations upon the top speed of vehicles. As it is proportional to the square of the velocity, its magnitude mounts rapidly as velocities are increased.

There are two kinds of drag — drag on surfaces which obtain a useful reaction from the airstream as well as a drag, and drag upon surfaces where the only reaction is the drag. A wing has both drag and lift. Drag on the wing is the price paid for lift, and is so accepted. A strut, or wire, or wheel creates no lift, and the drag is wholly undesirable. A drag of this type is called parasite drag. Careful streamlining and reduction of parts exposed to the airstream are ways of reducing parasite drag. The drag of a wing may be divided into profile drag and induced drag. Induced drag depends upon the lift coefficient and the aspect ratio of a wing. The induced drag coefficient may be expressed as

$$C_{D_i} = C_L^2/\pi(AR)$$

where C_{D_i} is the induced drag coefficient, C_L the lift coefficient, and AR the aspect ratio of the wing.

During a test, profile and induced drag are not separable. Parasite drag depends upon the surface roughness and shape of the object.

Profile drag of airfoils is the result of skin friction and turbulent wake. It is greatly influenced by the Reynolds number (scale effect) and by initial turbulence in the airstream. Although some authors have proceeded on the basis that this is the sole influence on profile drag coefficient, others have found that the profile drag coefficient has a small variation with coefficient of lift. However, the generally accepted theories of origin of aerodynamic forces imply that scale effects modify profile and parasitic drags only and are absent in lift and induced drag. Experience confirms the validity of theory except near the burble, or stall, attitude of the airfoil, where viscosity has an effect on lift.

Experiments in the wind tunnel show that factors affecting reaction of air on airfoils are:

(1) The relative velocity of the air and airfoil.
(2) Ratio of span to chord of the surface area.
(3) Density of the air.
(4) The angle of inclination of the airfoil to the airstream.

All this may be stated somewhat as follows:

$$F \sim R^n \alpha \rho S V^2$$

F is wind reaction, α the angle of attack of the wing, ρ the mass density of the air, S the surface area, V the air velocity, and R the Reynolds number.

If a proper constant K is inserted, the similarity can be made into an equality. K may also be made to include the effect of the Reynolds number,

angle of attack, and air density. The equation is then simplified to:

$$F = KSV^2$$

This reaction is neither perpendicular nor parallel to the wind stream. It is convenient to divide it into its components of lift and drag. Letting K_L and K_D be the corresponding coefficients.

$$\text{Lift } L = K_L SV^2$$

$$\text{Drag } D = K_D SV^2$$

There will be a different value of K for each angle of attack and each R, although the effect of the latter is usually minor.

The defect of this equation is that K is not dimensionless, as a true coefficient should be; also, the formula is not flexible with respect to air density. If it were rewritten:

$$R = C\rho SV^2$$

C would be dimensionless. The equation is usually written thus for drag:

$$D = \tfrac{1}{2} C_D \rho SV^2$$

because $\rho V^2/2$ is the pressure necessary to give air of mass density ϱ at a velocity of V. This is called the *dynamic pressure*. The drag is also $C_D qS$, where q stands for dynamic pressure. The drag coefficient C_D varies with angle of attack, but it is dimensionless. Consistent units have to be used. ρ is the ratio of the weight of the air, or fluid, in pounds per cubic foot, to the acceleration due to gravity or 32.2 ft/sec^2 (9.8 m/sec^2); S is the wing area, projected upon the plane of chords, in square feet, and V is the velocity in feet per second. C_D is the nondimensional drag coefficient. The subscript D is used when the coefficient refers to the *average* coefficient for the *entire* wing, and the lowercase letter d is used when the drag coefficient refers to the airfoil of unit width. The wind-tunnel test is used to establish the law of variation, and the results are plotted as a drag curve, with the coefficient of drag as the ordinate, and either coefficient of lift or angle of attack as the abscissa.

A few typical coefficients of drag are:

(1) Flat plate normal to airstream. Average value 1.28 often used, although subject to variation from AR (aspect ratio) and R.N. (Reynolds number).

Flat plate parallel to airstream. C_D = skin friction coefficient as there is no turbulent wake. Varies, 0.002–0.008 depending on initial turbulence and R.N.

(2) Sphere (S = projected area), about 4×10^5 critical R.N. Laminar boundary, 0.45; turbulent, 0.1.

(3) Cylinder, axis transverse to airstream (S = projected area), about 4×10^5 critical R.N. Laminar boundary, 0.7; turbulent, 0.3.

(4) Thin wing, infinite AR, R.N. 3.5×10^6. $C_{D_p} = 0.01$.

(5) Airplane. $C_D = C_{D_o} + C_L^2/C_{D_o}$ varies greatly, as it depends upon a large number of design and operational factors.

The drag of an object is subject to other factors also, such as compressibility of the fluid medium in which the object moves, and surface roughness.

Under supersonic conditions, the drag coefficient may be approximated by the following formula,

$$C_D = \frac{4\alpha^2}{\sqrt{M^2 - 1}}$$

where α is the angle of attack in radians, and M is the Mach number for the fluid speed considered.

Drag Studies in the Automotive Field

Leading automotive manufacturers in recent years have directed considerable research toward determining how the detailed shapes of various areas of a vehicle (automobile, truck, bus, etc.) affect aerodynamic drag, with particular emphasis on improving fuel economy as well as performance in crosswinds at high speeds. For example, studies have included a combination of aesthetic considerations with aerodynamic performance. Such studies become varied and complex because of the several accepted basic auto designs (fastback, hatchback, notchback rear ends, for example). Computer simulation is playing an increasing role in such research because predictions of aerodynamic flows by computer provide rapid preliminary evaluation of prototype shapes, prior to large-scale testing, as provided by wind tunnels. Many examples of drag coefficient research could be given.

One manufacturer (spring of 1987) devised an improved method for determining projected vehicle frontal areas and thus improved drag coefficient values. See Fig. 12. Examples from bus and truck manufacturers are given in Fig. 13. The application of color computer graphics is shown in Fig. 14.

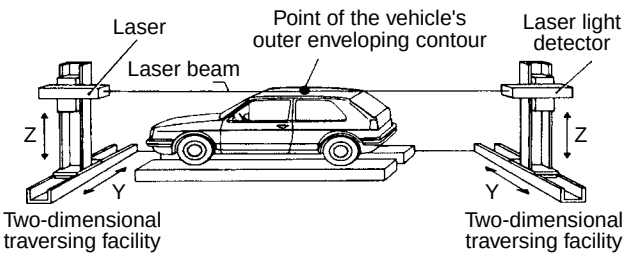

Fig. 12. In determining the drag coefficient of a vehicle, accurate measurements of the vehicle's contour must be made. The drag coefficient of a body in a flowing non-viscous fluid equals the ratio of twice the force on the body in the direction of flow to the product of the fluid's density, the square of the flow velocity, and the body's cross-sectional area. Although there are other methods for determining contour, such as shadow imaging; in contour *scanning*, the vehicle's outer enveloping contour can be measured point-to-point by using an optical projector guided perpendicular to the vehicle's longitudinal axis by a numerically controlled traversing facility. When the line of sight of the measuring device strikes the vehicle's contour, an appropriate signal is generated to trigger the coordinate recorder. In system shown here, a helium-neon laser is used as light source. (*Automotive Engineering*.)

Theory of Aerodynamic Compressibility

The "incompressible fluid" theory of classical hydrodynamics has proved useful for the estimation of aerodynamic parameters, and when applied to problems of low-speed flight has yielded sufficiently accurate results. It has been found, however, that the flow pattern about a body moving through the air at high speeds is affected to a large degree by changes in density resulting from compression or expansion of the fluid. Consequently, aerodynamic coefficients based on an incompressible-flow theory are in considerable error when applied to airplanes moving at high speeds. An understanding of compressible flows is, therefore, of the utmost importance to the designer of high-speed aircraft.

In the study of compressibility phenomena as applied to aerodynamic problems, airplane speeds are classified according to their relation to the speed of sound in air. The speed of sound is taken as a reference velocity because it is a function of fluid elasticity. As applied to compressible flows this means that the amount of pressure necessary to cause a given change in density in any fluid is proportional to the speed of sound in the fluid. Since the pressure is proportional to the square of the velocity, the velocity a body may attain before appreciable density changes occur is also proportional to the velocity of sound in the fluid. It is apparent, therefore, that the flow pattern about a body will be altered by density changes to a degree dependent upon the ratio of the velocity of the body to the velocity of sound. This ratio is known as the *Mach number* and is taken as an index of the effects of compressibility on the flow pattern. A curve showing the variation of the speed of sound with altitude is presented in Fig. 15. The local velocity of sound is directly proportional to the square root of the absolute temperature. Therefore, the variation of the speed of sound with altitude is essentially due to the variation in the temperature of the air.

In order to show quantitatively the changes in air density associated with increasing Mach number the following table has been prepared. This table is based on an adiabatic flow through a converging nozzle. M is the stream Mach number and ρ/ρ_s is the ratio of the corresponding air density to the density at static conditions.

M	ρ/ρ_s
0.2	0.981
0.4	0.925
0.6	0.841
0.8	0.742
1.0	0.635

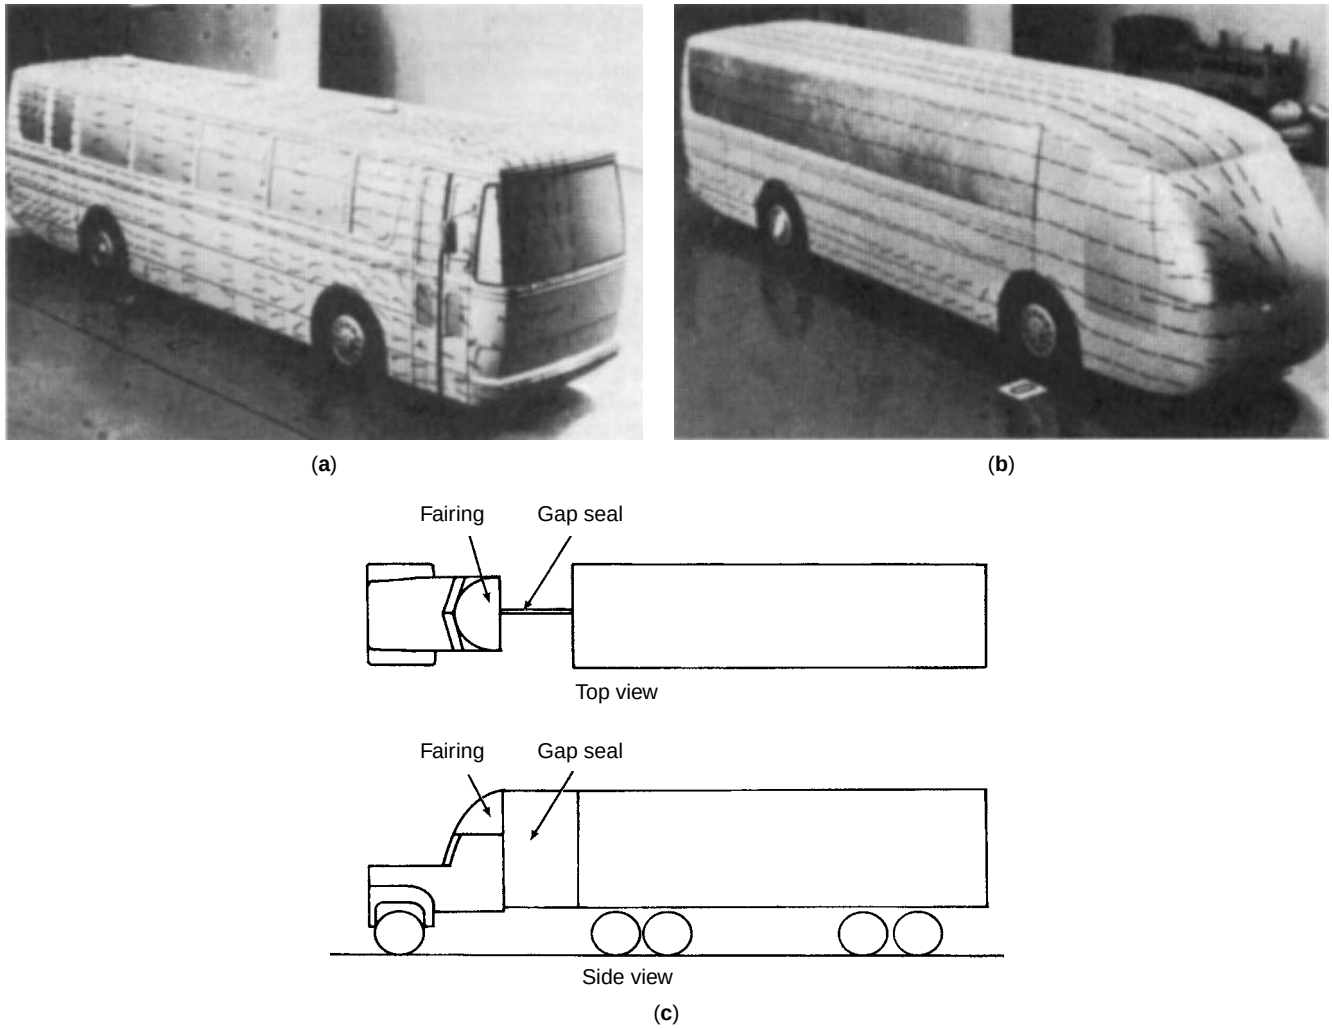

Fig. 13. Tractor-trailers and buses generally are large bluff bodies that do not have ideal aerodynamic shape. Because of the high replacement cost of these vehicles, various researchers have investigated the effects of "add-on" devices on the reduction of aerodynamic drag. One study on buses has shown that drag can be reduced as much as 27%, with fuel consumption reduction of 12%. A traditional bus front-end is shown in (**a**); an optimized, aerodynamically attractive front-end is shown in (**b**). This study was made using scaled-down models (50%) and testing in a wind tunnel.

In a study of tractor-trailers, it was concluded that conventional tractors do not have inherently lower drag coefficients than those with cab-over-engine tractors. It has been found that it is the streamlining of the tractor and the interference which it produces with the flow about the trailer that is important, not the type of tractor. As shown by (**c**), a streamlined cab-roof fairing and the gap seal were evaluated as to their effect on the drag distribution of the tractor-trailer combination. The fairing guides air around and over the trailer so that it does not impact on the front of the trailer and separate at its forward edges. The gap seal is a flat plate mounted vertically along the centerline of the vehicle between the tractor and trailer. It improves the horizontal flow through the gap due to crosswinds and hence reduces separation on the front of the trailer due to this flow. When used in conjunction with the fairing, it also acts to stabilize the wake of the fairing in gusty winds and thus acts to maintain the fairing's effectiveness.

The preceding discussion fully accounts for the effects of compressibility only at Mach numbers less than one, or at subsonic speeds. As air speeds approach and attain the velocity of sound, radical changes occur in the flow pattern which do not result entirely from changes in air density. The flow pattern in a perfect incompressible fluid is instantaneously influenced at all points by pressure changes occurring at any point in the flow field. A consideration of the theory of elasticity as applied to fluids, however, indicates that the effects of small pressure changes in a real fluid are transmitted throughout the fluid in the form of waves that travel at the speed of sound. It may be seen, then, that the effects of a pressure change that occurs behind the critical point at which the speed of sound has been reached cannot influence the flow field ahead of the point.

Since at the critical point the forward motion of the pressure waves is completely arrested by an airstream velocity equal to the velocity of wave propagation, a wave front is formed at the critical point. This wave front constitutes a sharp discontinuity in the flow; with this are associated large increases in pressure, density, and temperature and a decrease in velocity. Such a wave front with its attendant discontinuities is known as a shock wave. The flow field about a body traveling at or near sonic velocities will be radically different from that at low speeds.

Once the velocity has increased beyond the sonic range and attained a sufficiently high supersonic value, the shock wave will be forced downstream and the flow at the original point of shock will be comparatively smooth. However, the flow pattern at supersonic speeds will bear little resemblance to that which obtains at low speeds.

High-speed flight is greatly complicated by the compressibility phenomena that have been described. The following paragraphs give an outline of the more important considerations in the aerodynamics of high-speed flight.

The change in aerodynamic characteristics which results from fluid compressibility is greatest when shock waves form on some part of the airplane such as an airfoil or cowling. The forward velocity of the airplane that corresponds to the formation of shock waves is called the critical speed. The critical airplane speed is always less than the velocity of sound since the local velocity over the airfoil surfaces and other components is in excess of the forward speed of the airplane. The critical Mach number is the ratio of the critical airplane speed to the speed of sound.

The airfoil section usually predominates as the factor that controls the effects of compressibility on the characteristics of high-speed airplanes. The variation in pressure distribution around an airfoil as the Mach number is increased is shown in Fig. 16. Both flight and wind-tunnel tests

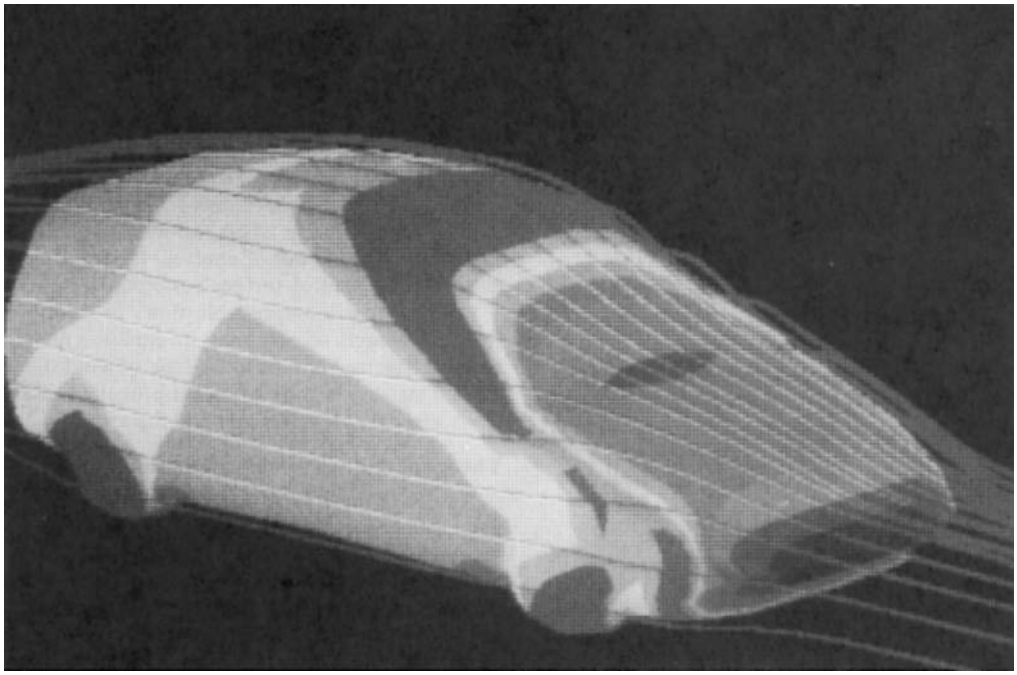

Fig. 14. Facsimile of color computer graphics image showing contours of computed surfaces and streamlines in the flow of an early evaluation of the aerodynamic characteristics of a proposed auto design. (*General Motors Corp.*)

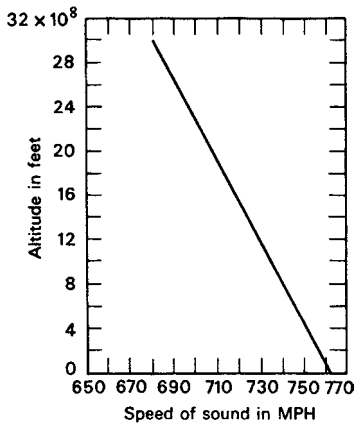

Fig. 15. Speed of sound as a function of altitude. Sea-level temperature, 60 °F (15.6 °C.)

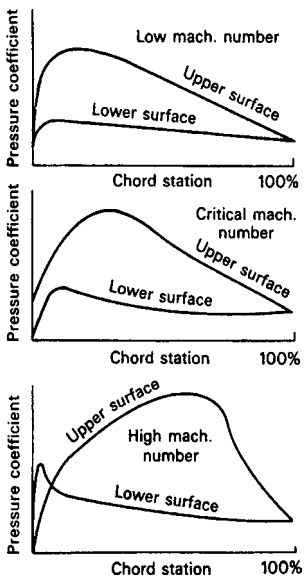

Fig. 16. Pressure distribution of an airfoil section at three different Mach numbers.

have shown that this change in pressure distribution affects the following important airfoil parameters:

(1) The drag coefficient, C_D.
(2) The slope of the lift curve $dC_l/d\alpha$.
(3) The pitching-moment coefficient, C_M.
(4) The maximum lift coefficient, $C_{l\,\max}$.

The drag coefficient suffers most, its value increasing tremendously as the critical Mach number is reached. The large increase in drag results not only from energy loss in the shock wave but also from the large positive pressure gradient existing across the shock. Such a pressure gradient causes boundary-layer separation which results in a wide, turbulent wake with its attendant-form drag. A curve is presented in Fig. 17, which shows qualitatively the variation of airfoil-drag coefficient with Mach number. In terms of airplane performance, the increase in drag that occurs at the critical speed indicates that a tremendous amount of power would be required for an airplane to fly through the sonic range of speeds and reach speeds above the speed of sound.

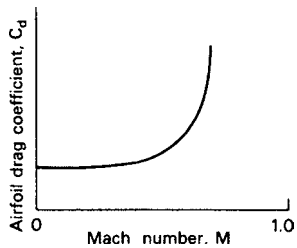

Fig. 17. Variation of airfoil drag coefficient with Mach number.

A loss in maximum lift coefficient occurs as the critical speed is approached. However, airplanes do not operate at high lift coefficients when traveling at high speeds. The changes in lift-curve slope and pitching-moment coefficients that occur with increasing Mach numbers are shown in Figs. 18 and 19. The variation of lift-curve slope with Mach number was calculated from Glauert's approximately correct theoretical relation, which states that the change in lift-curve slope is proportional to $1/\sqrt{1-M^2}$, where M is the free-stream Mach number.

The changes in pitching-moment coefficient and lift-curve slope indicate a considerable variation in the external forces acting on the lifting surfaces of airplanes traveling at high speeds. Unless the changes in C_M and

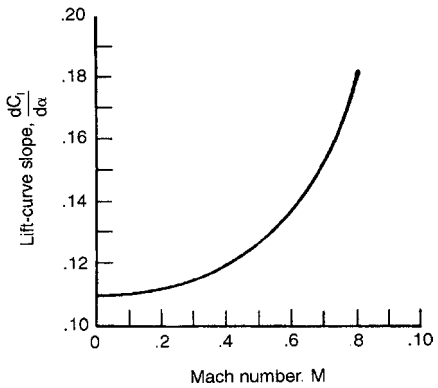

Fig. 18. Change of lift-curve slope with increasing Mach number.

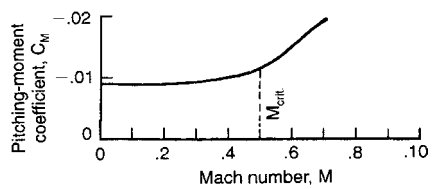

Fig. 19. Variation of pitching-moment coefficient with increasing Mach number.

$dC_l/d\alpha$ are taken into consideration in the design of high-speed airplanes, complete loss of control and stability may result at high speeds. The large turbulent wake discussed in connection with the drag of bodies at shock speeds also has an adverse effect on the control and stability. The angle of downwash and thus the trim of the airplane will change instantly when the wake widens and the plane may be thrown completely out of control. The large turbulent wake may also cause serious control-surface buffeting.

Knowledge of compressible flows is steadily increasing. The most fruitful methods of obtaining information about compressibility phenomena have been found in the field of wind tunnel testing and through careful instrumentation of rocket-propelled test vehicles for which the measured data are telemetered to the ground.

Theory of Aerodynamic Circulation

A mass of air in rotary motion is said to be in circulatory flow if its velocities at various radii from the center of rotation are of the proper magnitude to induce radial equilibrium of the circulating mass. Consideration of the requirements for equilibrium consists in balancing centrifugal forces against static pressures derived from Bernoulli's theorem and results in the specification that velocity of a particle must be inversely proportional to its radius from the center of rotation. Note that this is not like the motion of portions of a wheel, whose velocities are proportional to their radii. A simple case of circulation could be visualized as the flow pattern (concentric circles) induced by a rough cylinder rotating rapidly in still air.

If air is in circulation and no object such as a cylinder occupies the central core, the velocity at the center of rotation reaches a theoretical value of infinity. This is impossible and the center of circulatory flow must be occupied by a small core of air in simple rotary motion. Air in this condition is described as a free vortex. Exceptionally high velocities may exist at the edge of the rotary core, and in vortices of high circulatory strength such as tornadoes the atmospheric energy may reach the destructive proportions.

The strength of aerodynamic circulation (usually called the *circulation* and designated by symbol Γ) is the line integral of the tangential component of the velocity along any closed line encircling the vortex center, or some object.

$$\Gamma = \oint v dl$$

It has been proved that Γ has the same value for any closed path through the flow around the object (such as an airfoil, cylinder, etc.) and this fact is of value in various phases of aerodynamic analysis. A simple case of a flow pattern of concentric circles illustrates the constancy of Γ. The velocity at radius r is K/r and

$$\Gamma = \oint \frac{K}{r} dl = \oint \frac{K}{r} r d\theta = 2\pi K$$

Therefore Γ is not a function of r; its magnitude is constant throughout the flow pattern.

The generally accepted demonstration of the origin of lift on an airfoil employs a vortex circulation imposed on a rectilinear velocity field to produce the typical stream flow pattern, after which the aerodynamic forces are analyzed as originating from the impulse required to alter the momentum of the airstream and the static pressure. Fortunately, it is possible to analyze lift on the premise of frictionless flow. Viscosity effects do not enter until drag is sought. The dependence of lift of an airfoil of infinite span upon circulation Γ, free stream velocity V, and mass density ρ was proved independently by Kutta and Joukowski early in this century. Later Prandtl and others extended the "circulation theory" to cover the lift of finite wings. Joukowski's proof, considerably abbreviated, follows. The inherent tendency of an airfoil to create circulation is replaced by a bound vortex. A section of airfoil of unit span length is taken. The two flows are shown covering the same region in Fig. 20. Of course this figure does not represent the actual stream flow pattern since the latter would follow the vectorial combination of these two flows. Consider the region enclosed by the imaginary cylindrical surface at radius r from the vortex center. Let r be large enough to have circulatory velocity v small compared to rectilinear velocity V and integrate for vectorial change in momentum in this cylinder and vertical component of static pressure acting against it.

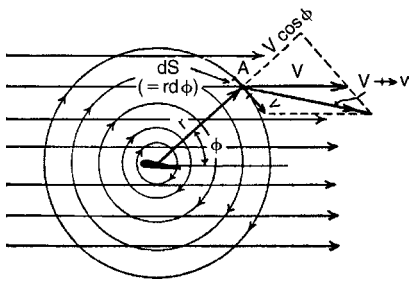

Fig. 20. Circulatory superimposed on rectilinear motion.

The velocity of circulation, v, is $\Gamma/(2\pi r)$ and its combination with V gives the direction and magnitude of the stream line at point A. The mass of air leaving the cylindrical region at A is $\rho ds\ (V\cos\phi)$ and its vertical component of velocity is $v\cos\phi$. The net vertical momentum in the cylindrical mass of air, due to inflow and outflow, is

$$\oint (\rho r d\phi)(V\cos\phi)\left(\frac{\Gamma}{2\pi r}\cos\phi\right)$$

which simplifies to

$$\frac{\rho\Gamma V}{2\pi}\oint \cos\phi d\phi$$

whence, by integration, the vertical impulse force is $(\rho\Gamma V)/2$. Since the change of momentum is downward the impulse force is upward, i.e., it is the lift. An integration of the horizontal component of momentum yields zero net momentum.

Proceeding next to evaluate the static pressure, note that Bernoulli's theorem applied at point A is covered by the following statement. Let p be the static pressure at A, and p_0 the free stream static pressure; then

$$p + \frac{\rho}{2}(V \dashrightarrow v)^2 = p_0 + \frac{\rho}{2}V^2$$

After expanding $(V \dashrightarrow v)^2$ and dropping all v^2 terms (since A was chosen to make v small relative to V),

$$p = p_0 - pVv\sin\phi$$

Since the second term on the right-hand side of this equation represents the variation from free stream pressure at point A, the lift (if any) will be

the line integral of its vertical component; i.e.,

$$\text{vertical pressure component} = \oint (\rho V v \sin\phi)(\sin\phi)(r d\phi)$$
$$= \rho \frac{V\Gamma}{2\pi} \oint \sin^2\phi d\phi$$
$$= \rho \frac{V\Gamma}{2}$$

The horizontal integral yields zero net pressure. The total lift per unit of span is the sum of that originating from momentum and that originating from pressure. From the preceding demonstration it is seen that each contributes equally to the total lift, which becomes $\rho V\Gamma$.

Theory and experiment show that Γ is always sufficient to cause the divided flow over the upper and lower surfaces to reunite at the trailing edge without reverse flow.

If the aerodynamic chord of the wing is parallel to the free stream velocity V, the lift is zero and obviously Γ is zero. As the angle of attack is increased Γ increases nearly proportionately. The strength of the circulation for an airfoil of chord c at aerodynamic angle of attack α_a is $\frac{1}{2}aVc\alpha_a$, where a is the proportioning factor. Since lift, $L, = \rho V\Gamma b$ (b = span), it also equals

$$a\alpha_a \frac{\rho V^2}{2}(bc)$$

Call $a\alpha_a$ the coefficient of lift, bc the area S, and $(\rho V^2)/2$ the dynamic pressure q; then the lift equation becomes

$$L = C_{Lq}S$$

If the wing has a finite span (i.e., definite tips), the bound vortex, assumed for the purpose of accounting for lift, is found to extend from the tips downstream as a free vortex. The effect of these tip vortices is to modify the air reaction since a downwash, w, is produced at the lifting line (see Fig. 21). The effect of downwash is to change the lift direction from L to L' since the relative wind, V_r, is now inclined. The angle $\in$ is always small, so L' may be considered of the same magnitude as L. However, L still remains the significant lift since the free stream velocity is V_0. Consequently, a drag D_i is introduced, although the original assumption of zero air viscosity remains in order.

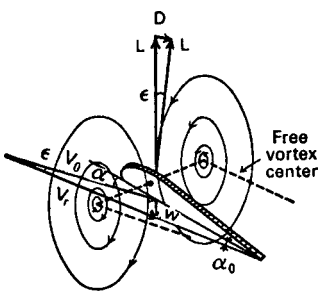

Fig. 21. Perspective of a section of airfoil subject to downwash from the free vortices at the tips.

This *induced drag* is a feature of the motion of ideal, frictionless air over a wing of finite span. The longer the span, the less the average effect of downwash (since in vortex motion $v \sim r^{-1}$) and the less the induced drag, but it will not disappear unless the span extends to infinity. By application of hydrodynamic theory beyond the scope of this article, aerodynamicists have shown that:

(1) Minimum induced drag for a given lift and span will be had if downwash is of constant magnitude over the span.

(2) Constant downwash will result from a bound vortex circulation strength of elliptical span-wise character.

(3) Elliptical span-wise Γ occurs on an untwisted airfoil of elliptical planform.

(4) With elliptical Γ a simple relation connects induced drag and aspect ratio.

$$D_i = L^2/\pi \text{AR}$$

where AR represents the aspect ratio.

This relation holds for the coefficient, too.

$$C_{Di} = C_L^2/\pi \text{AR}$$

As

$$\frac{D_i}{L} = \frac{C_{Di}}{C_L} = \frac{w}{V_0} \text{ (nearly)}$$

$$\alpha = \alpha_0 + C_L/\pi \text{AR}$$

It appears that a finite wing possesses an induced drag of C_{Di} not possessed by an infinite wing in ideal flow, also an induced angle of attack, requiring the angle of attack a of the finite span to be more than α_0 of an infinite span for the same lift per unit of span. The differences of induced drags of two wings of the same airfoil profile at the same lift coefficient but with different planforms follow naturally from the above:

$$C_{Di1} - C_{Di2} = \frac{C_L^2}{\pi}\left(\frac{1}{\text{AR}_1} - \frac{1}{AR_2}\right)$$

It is commonly assumed that the difference between the total drag coefficients of two wings of the same airfoil profile but different aspect ratios is the difference in induced drag. Likewise, the difference in necessary angle of attack to the free stream velocity for the same C_L is

$$\alpha_1 - \alpha_2 = \frac{C_L}{\pi}\left(\frac{1}{\text{AR}_1} - \frac{1}{AR_2}\right)$$

While these induced effects are premised on elliptical planform for the wing, they hold very well for rectilinear wings with elliptical tips and those with moderate taper ratio.

The lateral or span-wide distribution of lift on a wing depends on the planform and the distribution of downwash. Two cases are illustrated — an elliptical wing and a rectangular one. See Fig. 22.

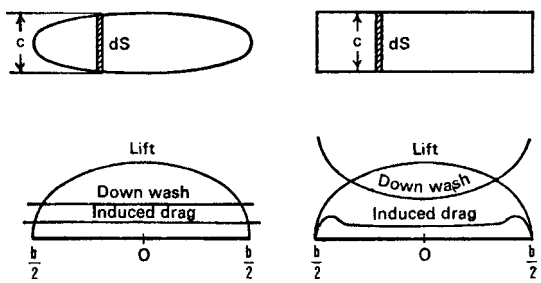

Fig. 22. Spanwise variations.

(1) The effect of downwash is to reduce the effective angle of attack and hence the lift coefficient. The lift of any lateral element dS is proportional to the product of C_L and c; hence the lift distribution of an elliptical wing is elliptical, while its induced drag, mirroring the downwash, is constant.

(2) The downwash strength increases near the tips of a rectangular wing. The lift coefficient accordingly declines, and lift falls off at the tip even though chord is maintained. Induced drag is strong at the tips.

Supersonic Aerodynamics

During World War II, certain fighter aircraft attained speeds that produced, on critical points of the airplane, local flow velocities of Mach 1.0 and higher, even though the airplane speed was less than that of sound. Since that time, much greater speeds have been attained. This performance introduced a new dimension to the science of aerodynamics that is better addressed in a separate article devoted exclusively to that topic. See **Supersonic Aerodynamics**.

For further coverage of aerostatics, see articles on **Balloon**; and **Dirigibles and Airships**.

AEROELASTICITY. The study of both the static and dynamic effects of aerodynamic forces on elastic bodies. The swaying of bridges, trees, smokestacks, and buildings are examples of the interplay of aerodynamic forces, inertia forces, and elastic properties of the structures. The flutter of flags, aircraft wings, and sails are more examples. For aircraft design, aeroelasticity is a most important study.

AEROGELS. Aerogels, solid materials that are so porous that they contain mostly air, were first prepared in 1931. Kistler used a technique known as supercritical drying to remove the solvent from a gel (a solid network that encapsulates its solvent) such that, as stated in his paper in Nature, "no evaporation of liquid can occur and consequently no contraction of the gel can be brought about by capillary forces at its surface." In the six decades since then, there have been significant advances made both in the use of new precursors to form gels and in the removal of solvent from them. These advances have greatly simplified the preparation of aerogels and, in turn, improved their economic viability for commercial applications. Increasingly an aerogel is defined in terms of its properties and not the way in which it is prepared.

Almost all applications of aerogels are based on the unique properties associated with a highly porous network. Envision an aerogel as a sponge consisting of many interconnecting particles which are so small and so loosely connected that the void space in the sponge, the pores, can make up over 90% of its volume. The ability to prepare materials of such low density, and perhaps more importantly, to vary the density in a controlled manner, is indeed what make aerogels attractive in many applications.

Sol–Gel Chemistry

Sol–gel chemistry involves first the formation of a sol, which is a suspension of solid particles in a liquid, then of a gel, which is a diphasic material with a solid encapsulating a solvent. A detailed description of the fundamental chemistry is available in the literature. The chemistry involving the most commonly used precursors, the alkoxides ($M(OR)_m$), can be described in terms of two classes of reactions:

$$\textit{Hydrolysis} \quad -M-OR + H_2O \rightarrow -M-OH + ROH$$

$$\textit{Condensation} \quad -M-OH + XO-M- \rightarrow -M-O-M + XOH$$

where X can either be H or R, an alkyl group

The important feature is that a three-dimensional gel network comes from the condensation of partially hydrolyzed species. Thus, the microstructure of a gel is governed by the rate of particle (cluster) growth and their extent of crosslinking or, more specifically, by the *relative* rates of hydrolysis and condensation.

Acid- and base-catalyzed gels yield micro- (pore width less than 2 nm) and meso-porous (2–50 nm) materials, respectively, upon heating. An acid-catalyzed gel which is weakly branched and contains surface functionalities that promote further condensation collapses to give micropores. This example highlights a crucial point: *the initial microstructure and surface functionality of a gel dictates the properties of the heat-treated product.*

Besides pH, other preparative variables that can affect the microstructure of a gel, and consequently, the properties of the dried and heat-treated product include water content, solvent, precursor type and concentration, and temperature.

In the preparation of a two-component system, the minor component can either be a network modifier or a network former. In the latter case, the distribution of the two components, or mixing, at a molecular level is governed by the *relative* precursor reactivity. Qualitatively good mixing is achieved when two precursors have similar reactivities. When two precursors have dissimilar reactivities, the sol–gel technique offers several strategies to prepare well-mixed two-component gels. Two such strategies are prehydrolysis, which involves prereacting a less reactive precursor and chemical modification, which involves slowing down a more reactive precursor. The ability to control microstructure *and* component mixing is what sets sol–gel apart from other methods in preparing multicomponent solids.

The sol–gel chemistry of organic materials is similar to that of inorganic materials. The first organic aerogel was prepared by the aqueous polycondensation of resorcinol with formaldehyde using sodium carbonate as a base catalyst.

Resorcinol–formaldehyde gels are dark red in color and do not transmit light. The preparation of melamine–formaldehyde gels, which are colorless and transparent, is also aqueous-based. Since water is deleterious to a gel's structure at high temperatures and immiscible with carbon dioxide (a commonly used supercritical drying-agent), these gels cannot be supercritically dried without a tedious solvent-exchange step. In order to circumvent this problem, an alternative synthetic route of organic gels that is based upon a phenolic–furfural reaction using an acid catalyst has been developed. The solvent-exchange step is eliminated by using alcohol as a solvent. The phenolic–furfural gels are dark brown in color.

Carbon aerogels can be prepared from the organic gels mentioned above by supercritical drying with carbon dioxide and a subsequent heat-treating step in an inert atmosphere.

Despite these changes, the carbon aerogels are similar in morphology to their organic precursors, underscoring again the importance of structural control in the gelation step. Furthermore, changing the sol–gel conditions can lead to aerogels that have a wide range of physical properties.

One of the fastest growing areas in sol–gel processing is the preparation of materials containing both inorganic and organic components, because many applications demand special properties that only a combination of inorganic and organic materials can provide. In this regard, sol–gel chemistry offers a real advantage because its mild preparation conditions do not degrade organic polymers, as would the high temperatures that are associated with conventional ceramic processing techniques. The voluminous literature on the sol–gel preparation of inorganic–organic hybrids can be found in several recent reviews and the references therein.

Preparation and Manufacturing

The development of aerogel technology from the original work of Kistler to about late 1980s has been reviewed. Over this period, supercritical drying was the dominant method in preparing aerogels. Several advances, have made possible the relatively safe supercritical drying of aerogels in a matter of hours. In recent years, the challenge has been to produce aerogel-like materials without using supercritical drying at all in an attempt to deliver economically competitive products.

Supercritical drying should be considered as part of the aging process, during which events such as condensation, dissolution, and reprecipitation can occur. The extent to which a gel undergoes aging during supercritical drying depends on the structure of the initial gel network. A higher drying temperature changes the particle structure of base-catalyzed silica aerogels but not that of acid-catalyzed ones. Gels that have uniform-sized pores can withstand the capillary forces during drying better because of a more uniform stress distribution. Such gels can be prepared by a careful manipulation of sol–gel parameters such as pH and solvent or by the use of so-called drying control chemical additives (DCCA).

Carbon dioxide is the drying agent of choice if the goal is to stabilize kinetically constrained structure, and materials prepared by this low-temperature route are referred to by some people as *carbogels*. In general, carbogels are also different from aerogels in surface functionality, in particular hydrophilicity.

However, even with carbon dioxide as a drying agent, the supercritical drying conditions can affect the properties of a product. Other important drying variables include the path to the critical point, composition of the drying medium, and depressurization.

For some applications it is desirable to prepare aerogels as thin films that are either self-supporting or supported on another substrate. All common coating methods such as dip coating, spin coating, and spray coating can be used to prepare gel films.

In all the processes discussed above, the gelation and supercritical drying steps are done sequentially. Recently a process that involves the direct injection of the precursor into a strong mold body followed by rapid heating for gelation and supercritical drying to take place was reported. By eliminating the need of forming a gel first, this entire process can be done in less than three hours per cycle. Besides saving time, gel containment minimizes some stresses and makes it possible to produce near net-shape aerogels and precision surfaces. The optical and thermal properties of silica aerogels thus prepared are comparable to those prepared with conventional methods.

Economic and safety considerations have provided a strong motivation for the development of techniques that can produce aerogel-like materials at ambient conditions, i.e., without supercritical drying. The strategy is to minimize the deleterious effect of capillary pressure which is given by:

$$P = 2\sigma\cos(\theta)/r$$

where P is capillary pressure, σ is surface tension, θ is the contact angle between liquid and solid, and r is pore radius.

The equation above suggests that one approach would be to use a pore liquid that has a low surface tension. In fact, with a pore liquid that has a sufficiently small surface tension, ambient pressure acid catalyzed aerogels with comparable pore volume and with bulk density to those prepared with supercritical drying have been produced.

For base-catalyzed silica gels, it has been shown that modifying the surface functionality is an effective way to minimize drying shrinkage. In particular, surface hydroxyl groups, the condensation of which leads to pore collapse, can be "capped off" via reactions with organic groups such as tetraethoxysilane and trimethylchlorosilane. This surface modification approach (also referred to as surface derivatization), initially developed for bulk specimens, has recently been applied to the preparation of thin films.

In changing surface hydroxyls into organosilicon groups, surface modification has an additional advantage of producing hydrophobic gels. This feature, namely the immiscibility of surface-modified gel with water, has led to the development of a rapid extractive drying process. This ambient pressure process offers improved heat transfer rates and, in turn, greater energy efficiency without compromising desirable aerogel properties.

Another approach to produce aerogels without supercritical drying is freeze drying, in which the liquid–vapor interface is eliminated by freezing a wet gel into a solid and then subliming the solvent to form what is known as a *cryogel*. The limited data available on freeze drying suggest that it might not be as attractive as the above ambient approaches in producing aerogels on a commercial scale.

TABLE 1. TYPICAL VALUES OF PHYSICAL PROPERTIES OF SILICA AEROGELS

Property	Values
Density, kg/m^3	3–500
Surface area, m^2/g	800–1000
Pore sizes, nm	1–100
Pore volume, cm^3/g	3–9
Porosity, %	75–99.9
Thermal conductivity, W/(m·K)	0.01–0.02
Longitudinal sound velocity, m/s	100–300
Acoustic impedance, kg/(m^2·s)	10^3–10^6
Dielectric constant	1–2
Young's modulus, N/m^2	10^6–10^7

Properties

Table 1 summarizes the key physical properties of silica aerogels. A range of values is given for each property because the exact value is dependent on the preparative conditions and, in particular, on density.

Applications

Aerogels are used in thermal insulation, catalysis, detection of high energy particles, piezoceramic, ultrasound transducers, integrated circuits, and as dehydrating agents.

AEROLITE. A general term for meteorites that are richer in the basic silicates than in nickel and iron. See also **Meteoroids and Meteorites**.

AEROLOGATION. See **Meteorology**.

AEROLOGY. 1. As officially used in the U.S. Navy until early 1957, same as meteorology; this usage was more administrative than scientific.

2. As a subdivision of meteorology, the study of the free atmosphere through its vertical extend, as distinguished from studies confined to the layer of the atmosphere adjacent to the earth's surface.

AERONOMY. The study of the upper regions of the atmosphere where ionization, dissociation, and chemical reactions take place.

AERONOMY OF ICE IN THE MESOSPHERE (AIM) MISSION. The Aeronomy of Ice in the Mesosphere, or "AIM", experiment is a NASA space mission designed to study the highest clouds in the earth's atmosphere–clouds at the edge of space. These clouds are made of frozen water, or ice crystals, just like some of the clouds that appear in the sky every day. Unlike the more common clouds, which form up to 5 miles above the earth's surface, these clouds are 50 miles high in a layer of the atmosphere called the mesosphere. Also unlike normal clouds, these clouds can only be seen near twilight, when the sun is just below the horizon and the sky is dark. For this reason, they are often called *noctilucent* clouds, or NLCs, because the word noctilucent means "night-shining". Scientists also call these clouds "polar mesospheric clouds", or PMCs for short, because they usually form only at high latitudes near the north and south poles. In recent years, however, several people have reported seeing NLCs at lower latitudes, even as low as 40 °FN in the continental United States, in Utah and Colorado. Also, NLCs seem to be getting brighter over time. Scientists do not understand why this is happening, and would like to find out. In particular, they wish to determine if these changes are caused by natural variations in the earth's atmosphere, or if they are influenced by human activities.

The overall goal of the Aeronomy of Ice in the Mesosphere (AIM) experiment is to resolve why Polar Mesospheric Clouds (PMCs) form and why they vary. By measuring PMCs and the thermal, chemical and dynamical environment in which they form, we will quantify the connection between these clouds and the meteorology of the polar mesosphere. In the end, this will provide the basis for study of long-term variability in the mesospheric climate and its relationship to global change.

The results of AIM will be a rigorous validation of predictive models that can reliably use past PMC changes and present trends as indicators of global change. This goal will be achieved by measuring PMC abundances, spatial distribution, particle size distributions, gravity wave activity, cosmic dust influx to the atmosphere and precise, vertical profile measurements of temperature, H_2O, OH, CH_4, O_3, CO_2, NO, and aerosols. These data can be obtained only by a complement of instruments on an orbiting spacecraft because of the need for global coverage and because extinction and foreground emissions compromise optical sensing from the ground.

With its three onboard instruments, the AIM spacecraft will collect data continuously as it orbits the globe. The instruments include:

- Cloud Imaging and Particle Size Experiment (CIPS), an imager that will take pictures of the clouds to show when and where they exist, as well as what they look like at various stages of formation.

- **Solar Occultation for Ice Experiment (SOFIE)**, will measure the temperature of the mesosphere and how much water vapor is present, to determine what combination of these is necessary to freeze the water into ice crystals that form PMCs. This instrument will also measure the amounts of other gases to tell scientists more about the chemistry and movement of air in the mesosphere that might lead to cloud formation or evaporation.
- Cosmic Dust Experiment (CDE), which will record how much dust enters the mesosphere from meteors. This is important because scientists wish to find out if a tiny speck of dust is necessary to provide a surface on which water vapor condenses and freezes; it is possible that without dust, PMCs are much less likely to form.

AIM will be launched aboard a Pegasus rocket from Vandenberg Air Force Base, California, in the spring of 2007. The expected mission life is 26 months.

Hampton University (HU) is the prime contractor with NASA and manages the programmatic aspects of the project, including the NASA interface, the subcontracts to the University of Colorado Laboratory for Atmospheric and Space Physics (LASP) and other participating universities, project reporting to NASA and manages other administrative efforts required. The Principal Investigator, Dr. James M. Russell III, at HU, leads the science, instrument, and spacecraft teams. AIM data will be analyzed and prepared for public archiving by Hampton University with the assistance of GATS Inc.

AEROPAUSE. A region of indeterminate limits in the upper atmosphere, considered as a boundary or transition region between the denser portion of the atmosphere and space. From a functional point of view, it is considered to be that region in which the atmosphere is so tenuous as to have a negligible, or almost negligible, effect on humans and aircraft, and in which the physiological requirements of man become increasingly important in the design of aircraft and auxiliary equipment.

AEROSOL. A colloidal system in which a gas, frequently air, is the continuous medium, and particles of solids or liquid are dispersed in it. Aerosol thus is a common term used in connection with air pollution control. Studies of the particle size distribution of atmospheric aerosols have shown a multimodal character, usually with a bimodal mass, volume, or surface area distribution and frequently trimodal surface area distribution near sources of fresh combustion aerosols. The coarse mode (2 micrometers and greater) is formed by relatively large particles generated mechanically or by evaporation of liquid from droplets containing dissolved substances. The nuclei mode (0.03 micrometer and smaller) is formed by condensation of vapors from high-temperature processes, or by gaseous reaction products. The intermediate or accumulation mode (from 0.1 to 1.0 micrometer) is formed by coagulation of nuclei. Study of the behavior of the particles in each mode has led to the belief that the particles tend to form a stable aerosol having a size distribution ranging from about 0.1 to 1.0 micrometer. The larger particles (in excess of 1.0 micrometer in size) settle, or fall out, whereas the very fine particles (smaller than 0.1 micrometer) tend to agglomerate to form larger particles which remain suspended. The nuclei mode tends to be highly transient and is concentration limited by coagulation with both other nuclei and also particles in the accumulation mode. It further appears that additional growth of particle size from the accumulation mode to the coarse mode is limited to 5% or less (by mass). Thus, the particulate content of a source emission and the ambient air can be viewed as composed of two portions, i.e., settle-able and suspended.

Both settle-able and suspended atmospheric particles have deleterious effects upon the environment. The settle-able particles can affect health if assimilated and also can cause adverse effects on materials, crops, and vegetation. Further, such particles settle out in streams and upon land where soluble substances, sometimes including hazardous materials, are dissolved out of the particles and thus become pollutants of soils and surface and ground waters. Suspended atmospheric particulate matter has undesirable effects on visibility and, if continuous and of sufficient concentration, possible modifying effects on the climate. Importantly, it is particles within a size range from 2 to 5 micrometers and smaller that are considered most harmful to health because particles of this size tend to penetrate the body's defense mechanisms and reach most deeply into the lungs.

The term aerosol is also applied to a form of packaging in which a gas under pressure, or a liquefied gas that has a pressure greater than atmospheric pressure at ordinary temperatures, is used to spray a liquid. The result of the spraying process is to produce a mist of small liquid droplets in air, although not necessarily a stable colloidal system. Numerous products, such as paints, clear plastic solutions, fire-extinguishing compounds, insecticides, and waxes and cleaners, are packaged in this fashion for convenience. Food products, such as topping and whipped cream, also are packaged in aerosol cans.

For a number of years, chlorofluorocarbons were the most popular source of pressure for these cans. Because of concern in recent years over the reactions of chlorofluorocarbons in the upper atmosphere of the earth that appear to be leading to a deterioration of the ozone layer, some countries have banned their use in aerosol cans. Manufacturers have turned to other gases or to conveniently operated hand pumps.

AEROSOL SIZE DISTRIBUTION. The amounts of different size particles of solids or liquids that are suspended in air as an aerosol. Particle size affects scattering of sunlight (see also **Mie Scattering** and **Rayleigh Scattering**) that makes blue skies, white clouds, and hazy smog, and that affects visibility. Size affects the nucleation capability of particles to form cloud droplets due to both the curvature effect and the solute effect. Relative amounts of different particle sizes can be used as a tracer for an air mass, such as indicating whether it originated over continents, oceans, urban areas, or rural areas. The total abundance of particles is often proportional to the total number density of cloud droplets, which affects the size to which these droplets can grow and their resulting evolution. See also **Mie Theory**.

AEROTHERMODYNAMIC BORDER. An altitude at about 100 miles, above which the atmosphere is so rarefied that the skin of an object moving through it at high speeds generates no significant heat.

AESTIVATION. Summer dormancy, the antithesis of the more familiar hibernation. As an example, the African lungfish is known to burrow down into the mud when the water begins to get low in the rivers and lakes where it lives. Here, even though the mud dries into a hard cake, the lungfish survives in a state of aestivation. Some have even been cut out along with the surrounding dirt and shipped abroad. When the mud again becomes moist with water, the lungfish becomes active and resumes normal activity.

AFFINE TENSOR AND FREE VECTOR. A quantity that behaves like a tensor under a linear (affine) coordinate transformation, but not under a general coordinate transformation is called an affine tensor. From an affine tensor it is possible to construct a *free vector*, that is, a vector not related to a given point (nonlocalized vector).

AFFINITY. The tendency of an atom or compound to react or combine with atoms or compounds of different chemical constitution. For example, paraffin hydrocarbons were so named because they are quite unreactive, the word *paraffin* meaning "very little affinity." The hemoglobin molecule has a much greater affinity for carbon monoxide than for oxygen. The free energy decrease is a quantitative measure of chemical affinity.

AFLATOXIN. See **Yeasts and Molds**.

AFRICAN TRYPANOSOMIASIS. An infection by the flagellate blood protozoan parasite *Trypanosoma brucei*, which causes a fatal neurological disease whose final stage in humans is *sleeping sickness*. There are two epidemiological and clinical variants of the parasite: *T. b. rhodesiense* which causes East African sleeping sickness and *T. b. gambiense* which causes West African sleeping sickness are carried by various species of tsetse fly (Glossinia) in Africa. (A third member of the complex, *T. b. brucei*, under normal conditions does not infect humans.). *T. b. gambiense* is found in foci in large areas of West and Central Africa. The distribution of *T. b. rhodesiense* is much more limited, with the species found in East and Southeast Africa. About 50 million people are at direct risk of contracting the disease, some 25,000 new cases being reported every year and thousands more going unreported in 36 subSaharan countries. Even more important than the direct threat to humans is the fact that domestic livestock are susceptible to trypanosomiasis. Between them, the trypanosome and the tsetse fly make some four million square miles 10.4 mil sq km (3.9 mil sq miles) of Africa uninhabitable for most breeds of dairy and beef cattle. However, dwarf, indigenous cattle and goats live and survive within the tsetse zone. Having little or no access to meat and dairy products, most of the human population is malnourished and susceptible to other diseases.

The Gambian form of trypanosomiasis, found in West and Central Africa, is without a known natural reservoir and is a milder, endemic disease associated with fly breeding near streams. The Rhodesian sleeping sickness of East and Central Africa is clinically more severe and is carried by tsetse flies that breed in savannas and brushlands.

When the trypanosome is ingested by the tsetse fly, it lodges in the midgut and undergoes a series of biochemical and structural changes. When the fly bites a mammal, metacyclic trypanosomes are introduced into the host's blood stream, where they rapidly differentiate to a form that can proliferate. In the human blood, cerebral fluid, lymph nodes, and other organs, the trypanosome appears as a motile, pleomorphic organism 15−30 micrometers long with a flagellum and undulating membrane.

A human bitten by an infected tsetse fly develops a small nodule (primary or trypanosomal chancre) at the site of skin penetration from which the organisms may be isolated. These protozoa, whose life cycle is complex, change form, multiply, and invade the bloodstream via the lymphatic system in a matter of weeks or months (Fig. 1). The trypanosomes are responsible for causing the clinical form of the disease, which includes severe headache, anemia, local edema, skin rashes, fever, and liver and/or spleen damage. Lymph nodes become enlarged and, in the advanced form of the disease, damage occurs to the central nervous system that causes the sleeping sickness phase. Lesions develop in the brain and, in some instances, in the myocardium. The disease has a high rate of mortality if left untreated. In the case of *T. b. rhodesiense*, death may ensue in several months.

The early stages of African trypanosomiasis, ie, before central nervous system involvement and the sleeping sickness take effect, can be best treated with intravenous suramin sodium (**1**, [CAS: 129-46-4] $C_{51}H_{34}N_6Na_6O_{23}S_6$), a compound with a dyelike structure. Suramin is most effective against *T. b. rhodesiense*, but has also been used against *T. b. gambiense* infection. The compound causes side effects such as nausea, photophobia, and peripheral neuropathy which disappear shortly after conclusion of administration. Because the drug is unable to pass the blood-brain barrier, prompt treatment of patients is essential. Suramin in combination with tryparsamide (**2**, Tryparsone [CAS: 554-72-3] $C_8H_{10}AsN_2NaO_4$) is an alternative that has been investigated. Pentamidine (**3**, [CAS: 100-33-4] $C_{19}H_{24}N_4O_2$), as the isethionate or methanesulfonate salt, has been used successfully against *T. b. gambiense*, but the compound also does

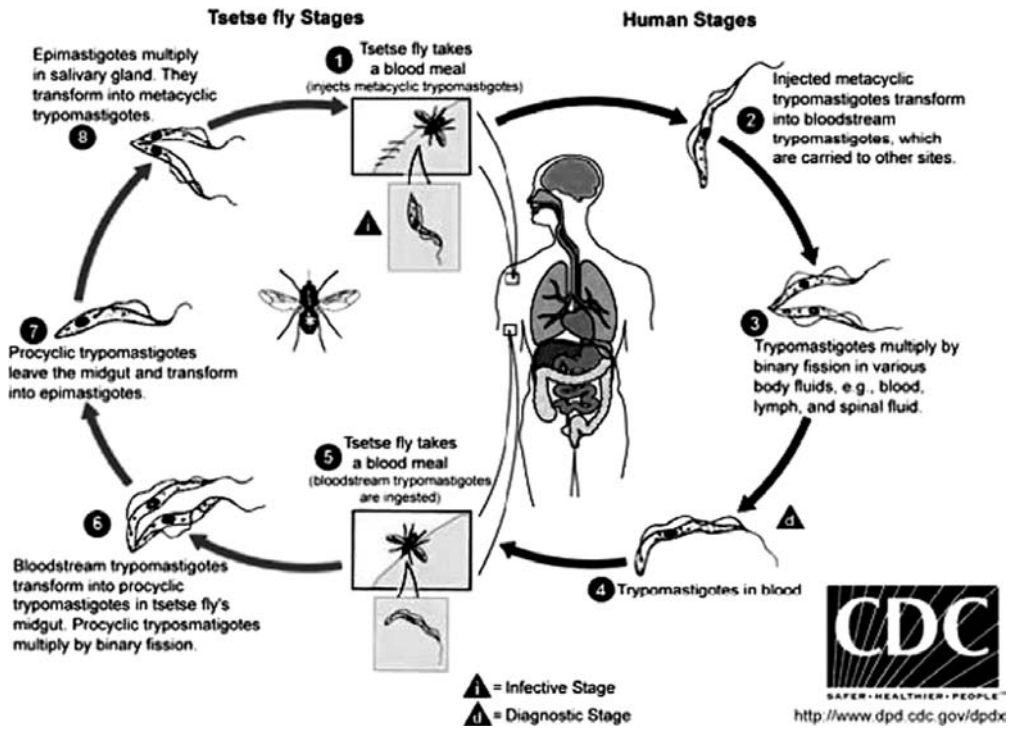

Fig. 1. During a blood meal on the mammalian host, an infected tsetse fly (genus *Glossina*) injects metacyclic trypomastigotes into skin tissue. The parasites enter the lymphatic system and pass into the bloodstream **1**. Inside the host, they transform into bloodstream trypomastigotes **2**, are carried to other sites throughout the body, reach other blood fluids (e.g., lymph, spinal fluid), and continue the replication by binary fission **3**. The entire life cycle of African Trypanosomes is represented by extracellular stages. The tsetse fly becomes infected with bloodstream trypomastigotes when taking a blood meal on an infected mammalian host (**4**, **5**). In the fly's midgut, the parasites transform into procyclic trypomastigotes, multiply by binary fission **6**, leave the midgut, and transform into epimastigotes **7**. The epimastigotes reach the fly's salivary glands and continue multiplication by binary fission **8**. The cycle in the fly takes approximately 3 weeks. Humans are the main reservoir for *Trypanosoma brucei gambiense*, but this species can also be found in animals. Wild game animals are the main reservoir of *T. b. rhodesiense*

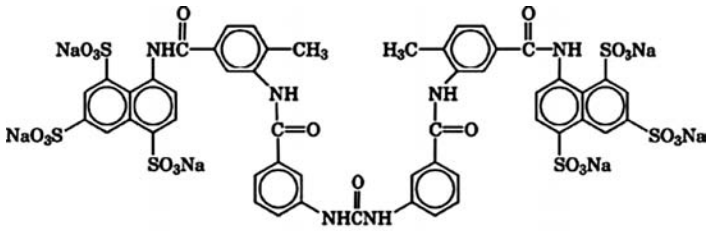
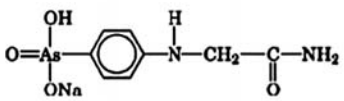
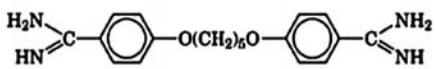
not enter the central nervous system and is not effective in advanced disease. It can cause severe side effects such as syncope, hypotension, hypoglycemia, vomiting, abdominal pain, and a peripheral neuropathy. Pentamidine **(3)** has been administered to large populations prophylactically against *T. b. gambiense*. This probably accounts for the appearance of resistant strains.



(1)

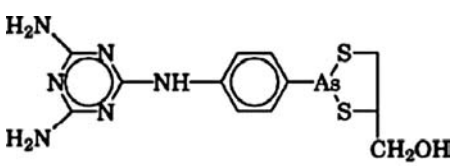


(2)



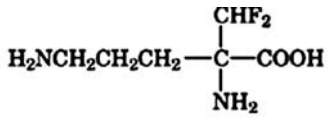
(3)

For late-stage disease, in which the central nervous system is implicated, the compound of choice until recently was melarsoprol (**4**, Mel B, Arsobal [CAS: 494-79-1] $C_{12}H_{15}AsN_6OS_2$) for *T. b. gambiense* or *T. b. rhodesiense*. The drug, administered intravenously, is a solution containing a combination of BAL (2,3-dimercaptopropanol) and the trivalent arsenic compound, melarsen oxide. Not only can the drug cause serious side effects such as intense dermal irritation, myocarditis, and renal and hepatic damage, but it is also responsible for death in 5% of patients. Resistance has developed to melarsoprol.

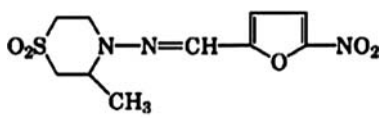


(4)

The first new treatment in 40 years that is showing great promise is eflornithine (**5**, [CAS: 67037-37-0] $C_6H_{12}F_2N_2O_2$). It is an irreversible inhibitor of ornithine decarboxylase that blocks putrescine biosynthesis in *T. brucei in vitro* and inhibits the growth and multiplication of the parasite *in vivo*. The drug, administered orally or parenterally, is relatively nontoxic and is effective in eliminating the parasite *T. b. rhodesiense* and, to a greater extent, *T. b. gambiense*. Late-stage disease is rapidly reversed, causing comatose sleeping sickness patients to regain consciousness. Eflornithine was approved for human use by the FDA in late 1990. Side effects associated with oral administration are diarrhea, nausea, and vomiting. There is a significant relapse rate. A mixture of eflornithine **(5)** and nifurtimox (**6**, [CAS: 23256-30-6] $C_{10}H_{13}N_3O_5S$, Lampit, Bayer 2502) shows good activity against *T. b. gambiense*. The former compound is also reported to potentiate the effect of melarsoprol in infected mice.



(5)



(6)

A combination of salicylhydroxamic acid (SHAM) and glycerol, although capable of destroying bloodstream trypanosomiasis, is less effective against infections involving the central nervous system.

Other approaches to elimination of the disease have involved eradication of the tsetse fly by spraying areas with insecticide or by distribution of sterile male flies. These methods, however, are expensive and have not been effective over extremely large territory as previously mentioned.

Centers for Disease Control and Prevention (CDC): http://www.cdc.gov/Ncidod/dpd/parasites/trypanosomiasis/default.htm.

ANN C. DEBALDO, College of Public Health, University of South Florida, Tampa, FL,

DANIEL L. KLAYMAN, Walter Reed Army Institute of Research

AFTERBIRTH. The membranes and placenta expelled from the uterus a short time after the birth of the child. See **Embryo**.

AFTERBODY. 1. A companion body that trails a satellite.

2. A section or piece of a rocket or spacecraft that enters the atmosphere unprotected behind the nose cone or other body that is protected for entry.

3. The afterpart of a vehicle.

AFTERBURNER. A device for augmenting the thrust of a jet engine by burning additional fuel in the uncombined oxygen in the gases from the turbine.

AFTERBURNING. 1. Irregular burning of fuel left in the firing chamber or a rocket after fuel cutoff.

2. The function of an afterburner, a device for augmenting the thrust of a jet engine by burning additional fuel in the uncombined oxygen in the gases from the turbine.

AFTERCOOLING. 1. The cooling of a gas after compression.

2. The necessary cooling of a reactor core after its shutdown by pumping a liquid or gas through it to carry off the excess heat generated by continuing radioactive decay of fission products within the core.

AFTERGLOW. 1. A broad, high arch of radiance or glow seen occasionally in the western sky above the highest clouds in deepening twilight, caused by the scattering effect of very fine particles of dust suspended in the upper atmosphere.

2. The transient decay of a plasma after the power has been turned off.

The decay time involved is a direct consequence of the charged particle loss mechanisms, such as diffusion and recombination. The magnitude of these quantities is determined by measuring the decay time under controlled conditions.

AFTER-IMAGE. The image "seen" after a portion of the retina has been fatigued by continued fixed stimuli. For instance, if one stares fixedly at a black cross-mark on a sheet of white paper for a minute or two and then suddenly looks at a blank wall, he will "see" a white cross-mark on the wall. If the image he stares at is colored, he will usually see an image of the complementary color on the wall. A green cross on the paper, for instance, will result in the appearance of a red cross on the wall. This is because the green-sensitive cones of the retina have become fatigued but the red-sensitive cones have not. The red-sensitive cones pick up the red light reflected from the wall, but the green-sensitive cones do not pick up the green light in a proper proportion.

AFTERSHOCK. See **Earth Tectonics and Earthquakes**.

AGAMIDS. Of the class *Reptilia*, subclass *Lepidosauria*, order *Squamata* (scaly reptiles), suborder *Sauria* (lizards), infraorder *Gekkota*, and family *Agamidae*, according to the classification of Grzimek (1972), the agamids are the counterpart in the New World to the iguanas of the Old World. See also **Iguanids**.

In most cases, these animals are strongly built, with long legs, a rather large head, and a long tail. Usually, the tail cannot be discarded and regenerated, as is the case with many lizards. The agamid body and tail are often covered by sturdy scales, almost always with a keel or ridge and sometimes with spines; the scales on the head are small and are not arranged symmetrically. The tongue is short and fleshy. Vision is acute, playing a greater role than the sense of smell. There are distinct eyelids covered with scales, and desert animals often have scales along the edges like eyelashes to protect the eyes against blowing sand. The auditory organ usually has an external eardrum. The diet consists mainly of insects; the adults of larger forms are often herbivores or omnivores. There are 34 genera, comprising altogether some 300 species.

Many species of these decidedly diurnal animals, particularly the larger forms, live in very dry, even desert-like regions. However, in southeastern Asia, countless agamids live on the ground, in trees, and even in the water of the tropical rain forest.

In general, agamids behave in such a way as to prevent excessive fluctuations in body temperature. Many desert dwellers sun themselves in the morning by positioning themselves perpendicular to the rays of the sun, so that they receive the most radiant energy. See Fig. 1. At the warmest time of day, in contrast, they make their bodies narrow and orient toward the sun, often with the belly raised as far as possible off the hot sand. In such desert animals, the scales on the belly are usually light in color, in order to absorb the least radiation from the sand or rock below. Other species live in crevices in large rocks or in a cave, and they retire to these shelters for a while each day to avoid the midday heat. The ground dwellers, in contrast to the aboreal agamids, are not laterally flattened, but rather are flat on the back and belly. Their coloring is also related to heat regulation; among the desert forms, one finds very dark lizards, colored so that they may lose excess heat by radiation more quickly when they are in the shade.

Agamids usually can change color as strikingly as chameleons. The colors of the head, in particular, reflect several different moods, including

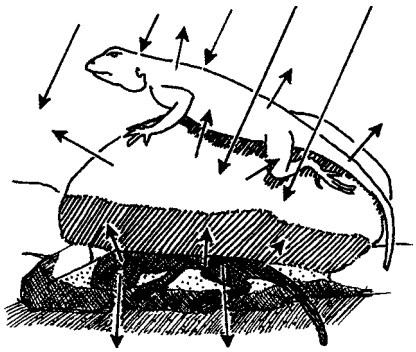

Fig. 1. The common agama controls its temperature in a sensible manner — warming up to its preferred temperature in the morning and positioning its body perpendicularly to the solar radiation, and cooling off by removing excess heat in the shade of a rock. (*After H. Schifter*.)

fear, eagerness to attack, and sexual excitation. Signals important in social behavior are the characteristic bobbing of the head and the less common waving of the forelegs. The males, in particular, bob their heads at regular intervals to display to a female and to intimidate possible intruders. See Fig. 2.

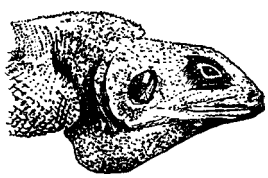

Fig. 2. Head of a male common agama showing the threat display. (*After H. Schifter*.)

Phylogenetic development of the agamids centered in the islands of Indonesia and on the southeastern Asian mainland. From there, certain ground-dwelling genera proceeded to colonize the Near East, Africa, and Australia. In the west it was primarily the genus *Agama*, which settled throughout Africa and the Near East. In the deserts of northern Africa and the Middle East, the spiny-tailed lizards are also found, and *Phrynocephalus* lives in western and central Asia. The range of the mountain-dwelling genus *Japalura* extends as far as northern China. The well-known moloch of Australia (genus *Moloch*) differs so radically from all other agamids that it probably has a long history of evolving in isolation. Later on, other agamids migrated to Australia, including, for example, the bearded lizard, the frilled lizard, the semi-aquatic *Physignathus*, and *Gonocephalus*. This last genus, which also inhabits southeastern Asia, is to be found on a number of Polynesian islands as well.

Some of the approximately sixty species of the agamids include:

1. The *Common Agama*.
2. The *Black-Necked Agama*, whose coloration is variable, but is predominantly green during courtship. His habitat is the savannas of southern and eastern Africa.
3. *Kirk's Rock Agama* has a low crest on the back, and the head of the male is often a bright orange. It dwells in the rocky desert areas, ranging from Zaire to Tanzania.
4. *Bibron's Agama* has a basically yellow-brown coloration. It lives in the rocky deserts of Morocco, Algeria, and Tunisia.
5. *Desert Agama* has rather inconspicuous coloring, except for displays of magnificent blue shading in the male during courtship. The head is short and, as a desert dweller, has well-developed eyelids. It feeds primarily on grasshoppers. Distribution is along the northern edge of the Sahara and the Arabian desert, from Morocco to Iraq.
6. The Hardun has legs and tail that are covered with scales bearing pronounced keels. Although predominantly insectivores, the hardun will also eat plants. It is found chiefly in rocky areas, often close to human settlements. Originally distributed from Arabia to western Turkey and on numerous islands of the Aegean Sea, more recently the hardun has been inadvertently transported to northern Greece, Corfu, and the vicinity of Alexandria (Egypt).

7. *Agama agilis* has eyelash-like scales that are similar to the conical lids of chameleons. The eyes are independently movable and thus can fixate different objects simultaneously. This agama inhabits southwestern Asia, from Arabia to Pakistan.
8. *Caucasian Agama* are found in groups of two to twenty-five animals that live and hunt together within a fairly well-defined territory, commonly at altitudes of up to 2700 meters, from Caucasia to Pakistan. In its homeland it is found everywhere in close association with humans, having succeeded in turning the continual destruction of the tropical African forests to its own advantage.
9. *Spiny-tailed lizards* live in rocky desert regions from Senegal to Egypt. They are quite variable in coloration, usually blackish with spots and cross bands which may be yellow, orange, red, and, less frequently, green. They are quiet animals and are easily supported in captivity. The variable color of the skin enables these lizards to carefully control heat radiation they receive. They are usually quite dark in the morning (to absorb radiation) and of a light color in the afternoon (to absorb less radiation).
10. *Toad-Headed Agamids* are among the smallest of the agamids. They range from Caucasia and Arabia to western China.
11. The *Moloch* of Australia is remarkable for its frightening appearance, with its body and tail covered with large spiny scales. Although of a dangerous appearance, the animal is quite harmless. It consumes ants at an exceedingly rapid rate, sometimes consuming nearly 2000 for one meal. The animal accommodates to arid conditions by using its highly specialized skin structure. The skin is equipped with threadlike canals between the scales. These canals suck up water in seconds, but do not discharge directly through the body wall because, if the skin were permeable, body water would escape. Rather, in a slow manner, the canals discharge into the corners of the mouth, stimulated by the animal's mouth movements.
12. *Frilled Lizard* has no dorsal crest, but does have an enormous "frill" (a fold of skin below either side of the head, supported by a row of cartilaginous extensions). Normally, the frill is kept folded back against the body, but during threat and courtship displays, the mouth is opened and the highly colored frill expands in a dramatic manner.
13. *Flying Dragons* (genus *Draco*) is unique among all present-day reptiles because of its specially adapted means for moving through the air. These "dragons" have two large, winglike flaps of skin, one on each flank. The last five to seven ribs are long, forming the movable skeleton that supports these "wings," which usually are folded flat along the body, but when the animal spreads them, it can perform long gliding flights from tree to tree. Other features of the body structure appear to have been "stylized" in favor of lightness and flying ability. There are sixteen species of *Draco*. All inhabit the tropical rain forest, often living high in the crowns of trees. Although flights of 60 meters have been observed, normally the distance is about 10 meters. *Draco* is widespread on the Indonesian islands.

The Chameleons. Most zoologists regard these animals as descendants of the ancient Agamidae because fossil forms have been found as early as the Cretaceous period. In addition to an ability to change their color, they have numerous distinct peculiarities, including their remarkable eyes, which can be moved independently. Each eye has a scaly lid in the form of a cone, with only a small opening in the middle for the pupil. Also, the tongue can be shot out to an extraordinary length, sometimes equal to the length of the animal. This is a great advantage for capturing prey at a comparatively long distance. Chameleons also are well adapted to arboreal life. The feet are modified and oppose one another much like the thumb and fingers of primates. The tail is a prehensile device, but, unlike many lizards, it cannot be broken off and subsequently replaced. Their diet includes spiders, grasshoppers, and stick insects, although in a terrarium they will accept other forms of insects. Larger chameleon species also consume small lizards and nesting mice. Their requirements for water generally are satisfied by dew from foliage.

Chameleons are egg layers — up to thirty or forty at a time, which are buried in the ground. However, some mountain species are ovoviviparous. Interesting characteristics of chameleons are shown in Fig. 3.

Some of the numerous species of chameleons include:

1. The *African Chameleon* may be up to nearly 40 centimeters in length. It ranges from western Africa to Ethiopia and Somalia, where it is subjected to annual climatic changes. Thus, the terrarium keeper must accommodate for such changes.
2. The *common chameleon* is found in tropical and southern Africa. It is aggressive and lives preferentially on low trees and bushes, but also descends to the ground, either to change its location or to dig a hole some 20 centimeters deep, in which it lays thirty to forty eggs. The principal enemy is the boomslang snake, which is seldom deterred by the chameleon's defensive mechanisms, including its changing displays of coloration, expanding dewlap, and hissing noises.
3. The *African Two-Lined Chameleon* is ovoviviparous. The animal is light to dark brown, with stripes along the sides of the body. Ten to twenty-five young are born alive at a time. The babies are only about 4 centimeters long, but grow to their full size of 11 to 16 centimeters in less than one year.
4. The *Dwarf Chameleon* is also ovoviviparous and is found in the cooler mountainous regions of southern Africa. Kastle observed that a dwarf chameleon runs away in a crouched posture, with the tail stretched out to impress and threaten its conspecifics, and that, when threatened, it expands its throat, opens its mouth, and rocks its body from side to side while wagging the head. The wagging motion, like the bobbing of the head in other species, also serves as a preliminary to mating.
5. The *Outstalet's Chameleon* lives on the island of Madagascar and ranges up to 63 centimeters in length. The creature is described as a quick and snappish animal, with a marked requirement for warmth. It principally feeds on large locusts, but can be adapted to a terrarium by feeding it with small mammals and lizards.

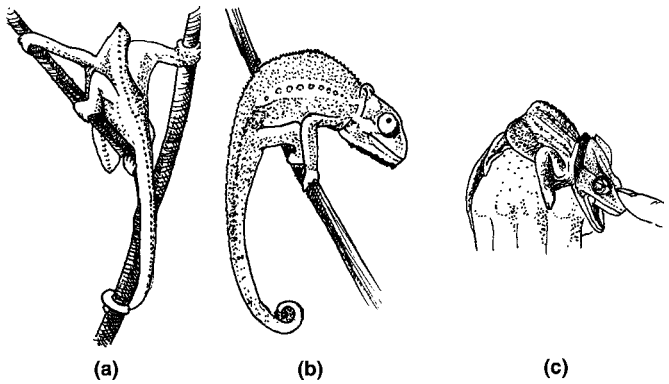

Fig. 3. Some characteristics of the dwarf chameleon (*Chamaeleo pumilus*), whose habitat is southern Africa. (**a**) To avoid falls, the animal climbs very carefully and anchors its body at five points, including the tail. (**b**) An old male dwarf chameleon. (**c**) Aggressive posture of the short-horned chameleon (*C. brevicornis*), whose habitat is Madagascar. Lobes behind the head are erected when irritated by a finger in a terrarium. (*After H. Schifter*.)

Other chameleons include the *Panther Chameleon*, found on the islands of Reunion and Mauritius; *Parson's Chameleon*, characterized by two processes on the snout; *Meller's Chameleon*, which is the largest chameleon outside of Madagascar; and the *Stumped-Tailed Chameleon* of Madagascar, among others.

AGAR. Sometimes called *agar-agar*, this is a gelatine-like substance which is prepared from various species of red algae growing in Asiatic waters. The prepared product appears in the form of cakes, coarse granules, long shreds, or in thin sheets. It is used extensively alone or in combination with various nutritive substances, as a medium for culturing bacteria and various fungi. See also **Gums and Mucilages**.

AGARICS *(Agaricaceae; Fungi).* This family of fungi is probably better known than any other, since it contains most of the plants commonly described by the names toadstool and mushroom, which popularly and mistakenly denote poisonous and edible fungi, respectively.

The Agarics are mostly fleshy fungi of that very definite structure, the familiar parasol-like toadstool. This is composed of convex pileus or cap,

usually supported on an evident stalk. The underside of the cap shows a series of radiating plates, or gills, which are formed in agaric fungi only, and so serve to separate them from all others. The two sides of the gills are covered with the microscopic spore-bearing bodies called basidia, which are club-shaped or cylindrical cells bearing spores, generally four each. Agarics vary in size from delicate species with a cap a millimeter or so in diameter, supported by a slender threadlike stalk, to massive forms twelve inches (30.5 centimeters) in diameter: the larger species form millions of spores. See Fig. 1.

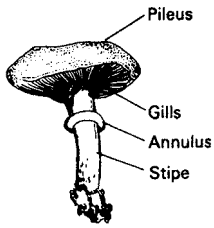

Fig. 1. Sporophore of a mushroom. (*Agaricus campestris*.)

The spores float in the air for considerable distances, and finally come to rest on some solid substance. Should this be favorable for germination, the spore puts out a slender tube, which elongates rapidly and penetrates the substratum, from which it absorbs substances necessary for its continued growth. Gradually this threadlike body, known as the mycelium, spreads through extensive masses of substratum, branching frequently as it does so.

Finally there is accumulated in the mycelium a supply of reserve food sufficient for fruiting: then, if atmospheric conditions, such as moisture and temperature, are suitable, the familiar toadstool appears, it being only the reproductive stage of the fungus. Its rate of growth is often phenomenal, as is also the force it may exert in its growth. Seemingly delicate bodies not only break open the hard-packed surface of the ground, but also may push aside pebbles of considerable weight. Not infrequently whole rings of toadstools appear in a field, springing to maturity in a single night — these are the familiar fairy rings, resulting from the growing outward from a common source of the unseen mycelium.

When the young fruit-body first comes up it is completely enclosed in a membranous skin known as the velum. As enlargement continues this skin is broken. Often traces of the velum remain in the form of flakes on the upper surface of the cap, and as a ring or annulus around the stalk. Attempts have been made to find in these characteristics a means for separating the edible from the poisonous species. However, no reliable distinction is found here. Actually, unless one is absolutely sure of the identity of a given species, the only safe rule is complete abstinence. Classification is based on the color of the spore-masses, and also the determination of the way in which the gills are attached to the stalk, the color changes shown as a cut or broken surface dries, and various other means.

A few species of Agarics, notably *Agaricus (Psalliota) campestris*, are extensively cultivated, and justly esteemed as food. Other species are violently poisonous, particularly species of the genus *Amanita*. Yet certain Siberian people use *Amanita muscaria*, a poisonous species, to produce a form of intoxication. Another common mushroom, the Inkycap, a species of *Coprinus*, has been used as a writing fluid, the substance of the toadstool breaking down into a fluid mass containing vast numbers of black spores. See **Basidiomycetes**.

Mushrooms are cultivated extensively in certain regions, usually in caves or specially constructed buildings. “Spawn” is prepared by inoculating grain, commonly rye, with spores or mycelium of the desired variety, and allowing the fungus to grow for a time. The spawn is spread as “seed” upon beds of compost where the fungus develops the characteristic mycelium described above. The compost is prepared from horse manure, including the bedding straw, from ground corn cobs, hay, or other organic materials. After the mycelium is established, the bed is covered by a thin layer of carefully selected soil. Usually thousands of mushrooms break through the soil at one time, and are harvested at the proper stage of growth. The entire growth takes place in the dark under controlled temperature and humidity.

AGAROSE GEL ELECTROPHORESIS. Agarose gel electrophoresis is a method used in biochemistry and molecular biology to separate DNA or RNA molecules by size. Typically, a DNA molecule is digested with restriction enzymes, and the agarose gel electrophoresis is used as a diagnostic tool to visualize the fragments. An electric current is used to move the DNA molecules across an agarose gel, which is a polysaccharide matrix that functions as a sort of sieve to help “catch” the molecules as they are transported by the electric current.

This technique has lots of applications. Generally speaking you can analyze DNA fragments that result from an enzyme digestion of a larger piece of DNA to visualize the fragments and determine the sizes of the fragments. In addition to its usefulness in research techniques, agarose gel electrophoresis is a common forensic technique and is used in DNA fingerprinting.

The phosphate molecules that make up the backbone of DNA molecules have a high negative charge. When DNA is placed on a field with an electric current, these negatively charged DNA molecules migrate toward the positive end of the field, which in this case is an agarose gel immersed in a buffer bath. The agarose gel is a cross-linked matrix that is somewhat like a three-dimensional mesh or screen. The DNA molecules are pulled to the positive end by the current, but they encounter resistance from this agarose mesh. The smaller molecules are able to navigate the mesh faster than the larger one, so they make it further down the gel than the larger molecules. This is how agarose electrophoresis separates different DNA molecules according to their size. The gel is stained with ethidium bromide so you can visualize how these DNA molecules resolved into bands along the gel.

AGASSIZ, JEAN LOUIS RODOLPHE (1807–1873). Agassiz was a Swiss -born American zoologist, paleontologist and geologist who introduced scientific zoology to the United States. The son of a Protestant pastor, Louis Agassiz was born in the Swiss town of Motier-en-Vuly, near Fribourg. He attended science lectures at various Swiss and German universities and received a doctorate, in 1829, from the University of Erlangen (Germany). The following year, he completed a medical degree at the University of Munich. His true love, however, was ichthyology. During his student years he had written a monograph on Brazilian fishes that earned him the praise of the French naturalist Georges Cuvier. He moved to Paris in 1832–1833 to work in his laboratory. His *Recherches sur les Poissons Fossiles*, a five-volume work superbly illustrated, was written in the tradition of Cuvier. Agassiz introduced a new classification for fish, a major improvement. Tireless, the naturalist also managed to publish abundantly on fossil mollusks and echinoderms, fish embryology and geographical distribution.

From 1832 to 1846, Agassiz taught natural history at a new college in the Swiss town of Neuchâtel. There, at the Hôtel des Neuchatelois, he established a research center to study the Alps’ glaciers. He compared the glacial formations of Switzerland to those of Scotland. After William Buckland found further evidence of glaciation in Scotland, he posited the existence of an ‘Ice Age’. Agassiz turned local geological observations into a theory of a continental scope. His concept was quickly espoused by fellow scientists, such as Sir Charles Lyell and Charles Darwin. Agassiz’ work on fossil fishes and glaciers made him an important scientist, but he would also become a prominent public figure during the American portion of his life. See also **Ice Ages**.

In 1846, Louis Agassiz was invited to the United States to deliver the Lowell Lectures in Boston. He then toured the eastern part of the United States, lecturing on comparative embryology. Foreseeing new opportunities, he decided to settle there with his children, after the death of his first wife. He was appointed Professor of Zoology and Geology at Harvard's Lawrence Scientific School (1847), a position he held until his death. America offered the energetic Agassiz the possibility to explore a novel natural environment; his observations fuelled his monumental Contributions to the Natural History of the United States, of which only four volumes were eventually published. But it is as a public man that Agassiz flourished in America. He gave public lectures, raised funds and established institutions. At Harvard, he founded the Museum of Comparative Zoology, of which he was the curator from 1859. He convinced other scientists to create the National Academy of Sciences in 1863, and was the founder of Anderson School of Natural History (1873) on Penikese Island in Massachusetts, both a summer school and a marine station. As he got more involved in public duties, Agassiz did less and less original research. Though his own contributions to natural history confirmed evolution, he nonetheless always rejected Darwin's views and believed instead in successive creations resulting from divine intervention.

AGATE. Agate is a variety of chalcedony, whose variegated colors are distributed in regular bands or zones, in clouds or in dendritic forms, as in moss agate.

The banding is often very delicate with parallel lines of different colors, sometimes straight, sometimes undulating or concentric. The parallel bands represent the edges of successive layers of deposition from solution in cavities in rocks that generally conform to the shape of the enclosing cavity.

As agate is an impure variety of quartz it has the same physical properties as that mineral. It is named from the river Achates in Sicily where it has been known from the time of Theophrastus.

Agate is found in many localities; India, Brazil, Uruguay, and Germany are notable for fine specimens.

Onyx is a variety of agate in which the parallel bands are perfectly straight and can be used for the cutting of cameos. Sardonyx has layers of dark reddish-brown carnelian alternating with light and dark colored layers of onyx.

See also **Chalcedony**; and **Quartz**.

AGAVE *(Amaryllidaceae)*. A large genus of plants, particularly abundant in Mexico, in which the thick rigid leaves form a basal rosette, from the center of which rises the tall flower stalk. Because of the time required to store sufficient food reserves for flowering, certain species, notably *Agave americana*, are called century plants from the belief that they flower but once a century; actually flowering may occur in from 5 to 50 or more years. Once started, the flower stalk develops very rapidly, requiring immense quantities of sap. In Mexico, the flower stalk is cut off early in its formation and the stump scooped out to form a cup into which quantities of sweet sap exude. This sap is collected and fermented to form pulque, a strong drink with an unpleasant odor. Distilled pulque gives a more potent drink, mescal. From the leaves of several species, particularly *Agave sisalana* and *A. fourcroydes*, are obtained fibers. These fibers occur as sclerenchyma sheathes surrounding the vascular bundles in the leaves. To obtain the fibers, the leaves are cut off and the spiny tip and margin removed. Machines then heat and scrape the leaves and wash them until the clean fibers are obtained. These are then dried either in the sun or by artificial heat, and are ready for export under the name of sisal or henequen, according to the species from which they were obtained. Many species of *Agave* are cultivated for their ornamental value. See **Century Plant**.

AGENT ORANGE. Common name for a 50–50% mixture of the herbicides 2,4,5-T and 2,4-D, once widely used by the military as a defoliant. The mixture contains dioxin as a contaminant. See also **Dioxin**; and **Herbicide**.

AGE-RELATED MACULAR DEGENERATION. Age-related macular degeneration (AMD) is a progressive disorder of the tiny central part of the retina, called the macula that gradually destroys central vision, making reading or driving difficult or impossible. Although some peripheral vision remains, a person with macular degeneration has increasing difficulty in reading, watching television, or even recognizing friends.

Because it is an age-related disease, the incidence of AMD is growing as the mature population increases. An estimated 400,000 Americans develop a serious form of the disease every year.

Although the macula occupies only 2% of the retina, it contains about 25% of the light-sensing cone cells, which are specialized for daylight vision. AMD occurs when this central part of the retina and the layer of cells underneath it, which is the retinal pigment epithelium, begin to deteriorate, for reasons that are not clear. Genetics may play a role in some cases, because the disease can run in families.

There are two forms of AMD, dry and wet. The "dry" form, which accounts for 85 to 90% of all cases, does not cause blindness but does cause a loss of central vision that can produce grayness, haziness, or a blind spot in the central area of vision. In the dry form of the disease, tiny white deposits called drusen accumulate in the retina, and there is a thinning of macular tissue. The cause is unknown, although lifetime exposure to sunlight and smoking may increase the risk. In "wet" AMD cases, which account for 10 to 15% of all cases, abnormal blood vessels grow under the retina, scarring or destroying retinal tissue, and often causing sudden blindness. The wet form causes most AMD-related blindness.

The symptoms of AMD are blurred vision, loss of color perception, a dark or empty spot in the center of the field of vision, and seeing crooked lines that are really straight. The condition can be diagnosed in several ways: with an ophthalmoscope, a slit lamp lens, an Amsler Grid test, photographing the back of the eye, fluorescein angiography, and/or macular pigment density testing.

Several techniques are used to treat wet AMD:

1. Laser photocoagulation surgery uses a powerful beam of light to attack the abnormal blood vessels. Early diagnosis is important because this treatment is effective only in the early stages of the disease. The surgery often does not stop the progression of abnormal blood vessels, so repeat treatments are needed. The surgery can destroy some healthy tissue, causing some loss of vision.
2. Still somewhat experimental, photodynamic therapy uses verteporfin (brand name Visudyne), a photosensitive dye that goes to the abnormal blood vessels. Light from a low-powered laser triggers a chemical reaction that destroys the blood vessels. Photodynamic therapy generates less heat than photocoagulation, and thus causes less damage to healthy tissue.
3. Another treatment involves surgery to detach the retina and rotate it, so that the macula is no longer in the region of abnormal blood vessel growth.
4. Surgery can also be used to remove the abnormal blood vessels.
5. Thalidomide, notorious for causing birth defects, is being tried as a treatment because it blocks blood vessel development.

There is evidence that chemicals called antioxidants, which include vitamins C and E, can protect the macula. So can carotenoids, which include beta-carotene, and the mineral selenium.

Field trials to determine whether vitamin therapy can be effective against macular degeneration have begun. The National Institutes of Health has started a study to determine whether estrogen replacement after the menopause can prevent or slow the progression of AMD.

Vision Rx, Inc., Elmsford, NY

AGGLOMERATE. A term proposed by Sir Charles Lyell in 1831 for coarsely graded volcanic ejectamenta similar in appearance to ordinary conglomerates or breccias. An extremely thick and widespread accumulation of so-called agglomerates occurs on the borders of the Yellowstone Park. These deposits, however, include numerous beds of water-laid pebbles, gravels and sands, the latter containing fossil plants of early tertiary age.

Because of the various interpretations of the term, it should be defined in context.

AGGLOMERATION. This term connotes a gathering together of smaller pieces or particles into larger size units. This is a very important operation in the process industries and takes a number of forms. Specific advantages of agglomeration include: increasing the bulk density of a material; reducing storage-space needs; improving the handling qualities of bulk materials; improving heat-transfer properties; improving control over solubility; reducing material loss and lessening of pollution, particularly of dust; converting waste materials into a more useful form and reducing labor costs because of resulting improved handling efficiency.

The principal means used for agglomerating materials include (1) compaction, (2) extrusion, (3) agitation, and (4) fusion.

Tableting is an excellent example of compaction. In this operation, loose material, such as a powder, is compressed between two opposing surfaces, or compacted in a die or cavity. Some tableting machines use the action of two opposing plungers that operate within a cavity. Resulting tablets may range from $\frac{1}{8}$ to 4 inches (3 millimeters to 10 centimeters) in diameter. Uniformity and dimensional precision are outstanding. Numerous pharmaceutical products are formed in this manner, as well as some metallic powders and industrial catalysts.

Pellet mills exemplify the use of extrusion. In some designs the charge material is forced out of cylindrical or other shaped holes located on the periphery of a cylinder within which rollers and spreaders force the bulk materials through the openings. A knife cuts the extruded pellets to length as they are forced through the dies.

The *rolling drum* is the simplest form of aggregation using agitation. Aggregates are formed by the collision and adherence of the bulk particles in the presence of a liquid binder or wetting agent to produce what essentially is a "snowball" effect. As the operation continues, the spheroids become larger. The strength and hardness of the enlarged particles are determined by the binder and wetting agent used. The operation is followed by screening, with recycling of the fines.

The *sintering process* utilizes fusion as a means of size-enlargement. This process, used mainly for ores and minerals and some powdered metals, employs heated air that is passed through a loose bed of finely ground material. The particles partially fuse together without the assistance of a binder. Sintering frequently is accompanied by the volatilization of impurities and the removal of undesired moisture.

The *spray-type* agglomerator utilizes several principles. Loosely bound clusters or aggregates are formed by the collision and coherence of the fine particles and a liquid binder in a turbulent stream. The mixing vessel consists of a vertical tank, around whose lower periphery are mounted spray nozzles for introduction of the liquid. A suction fan draws air through the bottom of the tank and creates an updraft within the mixing vessel. Materials spiral downward through the mixing chamber, where they meet the updraft and are held in suspension near the portion of the vessel where the liquids are injected. The liquids are introduced in a fine mist. Individual droplets gather the solid particles until the resulting agglomerate overcomes the force of the updraft and falls to the bottom of the vessel as finished product.

AGGLUTINATION. 1. The gathering of particles. 2. The clumping together of bacteria or cells, resulting often from their reaction with the corresponding immune or modified serum.

AGGLUTININ. One of a class of substances found in blood to which certain foreign substances or organisms have been added or admixed. As the name indicates, agglutinins have the characteristic property of causing agglutination, especially of the foreign substances or organisms responsible for their formation.

AGGRADATION. In geology, the building up of the surface of the earth by deposition, as of sediment by a river in its valley. More specifically, the up-building caused by a stream so as to establish and maintain a uniform grade or slope. The term also is used sometimes as a synonym for accretion, as in the case of development of a beach. See also **Accretion**; and **Alluvial Fan**.

AGGREGATE. The solid conglomerate of inert particles which are cemented together to form concrete are called aggregate. A well-graded mixture of fine and coarse aggregates is used to obtain a workable, dense mix. The aggregate may be classed as fine or coarse depending upon the size of the individual particles. The specifications for the concrete on any project will give the limiting sizes that will distinguish between the two classifications. Fine aggregate generally consists of sand or stone screenings while crushed stone, gravel, slag or cinders are used for the coarse aggregate. The aggregates should be strong, clean, durable, chemically inert, free of organic matter, and reasonably free from flat and elongated particles since the strength of the concrete is dependent upon the quality of the aggregates as well as the matrix of cementing material. See also **Concrete**.

AGGREGATION. (1) This overall operation may be considered to include the more specific designations of *agglutination*, *coagulation*, and *flocculation*. These terms imply some change in the state of dispersion of sols or of macromolecules in solution.

Agglutination generally refers to the aggregation of particulate matter mediated by an interaction with a specific protein. More specifically, the term refers to antigen–antibody reactions characterized by a clumping together of visible cells, such as bacteria or erythrocytes. The distinguishing feature of these reactions appears to be the presence of special areas where the orientation of active groups permits specific interaction of antigen with antibody. There is evidence that the forces involved may include hydrogen bonding, electrostatic attraction, and London-van der Waals forces. The clumping of the fat globules in milk has been described as an agglutination by the proteins of the euglobulin fraction. When the fat globules are dispersed in a dilute salt solution, the addition of this protein fraction induces normal creaming. Although this action is nonspecific, the same protein fraction causes agglutination of certain bacteria when they are added to milk.

Coagulation of a hydrophobic sol may be brought about by the addition of small amounts of electrolytes. Coagulation may be rapid, occurring in seconds, or slow, requiring months for completion. The resultant coagula contain relatively small proportions of the dispersion medium, in contrast with jellies formed from hydrophilic systems. Sometimes it is found that what at first appeared to be a homogeneous liquid becomes turbid and distinctly nonhomogeneous. Systems which are intermediate between true hydrophobic sols and hydrophilic sols are encountered frequently, so that in common usage the word *coagulation* is applied to such diverse phenomena as the clotting of blood by thrombin or the clotting of milk by rennin.

Flocculation is generally considered synonymous with coagulation, but is widely used in connection with certain kinds of applications. If one considers only hydrophilic systems, it is apparent that an important factor in flocculation is the solvation of the particles, despite the common presence of an electric charge. Since stability appears to depend upon solute-solvent interactions and solubility properties, flocculation can frequently be brought about by either of two pathways. The addition of salts may compress the double layer, leaving the macromolecules stabilized by a diffuse solvation shell. The addition of alcohol or acetone will dehydrate the particles, leading to instability and flocculation. Alternatively, the alcohol or acetone may be added first, which will convert the particle to one of hydrophobic character stabilized largely by the electric double layer. Such a sol can be coagulated by the addition of small amounts of electrolytes.

(2) The process of clumping together of snow crystals following collision as they fall to form snowflakes. This process is especially important near the melting layer where snow particles stick to each other more easily because of the liquid water on the surface. It also occurs at lower temperatures especially between dendritic snow crystals and occasionally

rosette crystals in cirrus. See also **Colloid Systems**; and **Snow and Snowmelt**.

AGGRESSIN. A product of bacterial metabolism that impairs the defensive mechanisms of the blood of the host.

AGING. See **Gerontology**; and **Geriatrics**.

AGONIC LINE. The line through all points on the earth's surface at which the magnetic declination is zero; that is, the locus of all points at which magnetic north and true north coincide.

This line is a particular case of an isogonic line. The position of this line exhibits variations in time, but in 1995 was so located that it emanated from the north magnetic pole, trended southward through the Great Lakes region, left the American mainland near Mississippi, cut across South America to near Buenos Aires, thence through the south magnetic pole, and up in an irregular path on the other side of the earth to return to the north magnetic pole. At the present time, the North American segment of the agonic line is drifting very slowly westward.

See also **Aclinic Line**; and **Isogonic Line**.

AGRANULOCYTOSIS. This is a potentially serious syndrome in which the white cells may be greatly decreased or almost absent from circulation. Because the granulocytes are important in protecting the body against infection, an individual deprived of these defensive forces for long may have an overwhelming invasion of the bloodstream and organs with dangerous disease-producing organisms. See also **Blood**. Important symptoms include general weakness, prostration, headache, shaking chills, and progressive ulcerative throat lesions. Diagnosis must be confirmed by studies of the bone marrow.

The syndrome of agranulocytosis may result from an overwhelming infection, releasing toxins specifically destructive to the bone marrow and lymphatic systems. It may develop secondary to allergic sensitization to drugs with antigenic properties, such as aminopyrine, cimetidine, potassium-sparing diuretics, procainamide, propanolol, and sulfapyridine. Industrial toxins, particularly benzol, may damage the marrow similarly.

AGREEMENT (Coefficient of). This coefficient relates to the situation where m observers each provide paired comparisons for n objects. A coefficient of agreement between the verdicts of the m observers is given by

$$u = \frac{8\sum}{m(m-1)(n-1)n} - 1$$

where $\sum$ is the sum of the number of agreements between pairs of judges.

The coefficient may vary from $-1/(m-1)$, if m is even, or $-1/m$, if m is odd, up to $+1$ if there is complete agreement.

AGRICULTURAL CLIMATOLOGY. In general, climatology as applied to the effect of climate on crops. It includes especially the length of the growing season, the relation of growth rate and crop yields to the various climatic factors and hence the optimal and limiting climates for any given crop, the value of irrigation, and the effect of climatic and weather conditions on the development and spread of crop diseases. This discipline is primarily concerned with the space occupied by crops, namely, the soil and the layer of air up to the tops of the plants, in which conditions are governed largely by the microclimate. See also **Microclimate**.

AGRICULTURAL DROUGHT. See **Meteorology**.

AGRICULTURAL METEOROLOGY. See **Meteorology**.

AGROSTOLOGY. The science of grasses, including classification, management, and utilization. See **Grasses**.

AGULHAS CURRENT (also called Agulhas Stream). A predominantly southwestward-flowing current of the Indian Ocean; one of the swiftest of ocean currents.

Throughout the year, part of the south equatorial current turns south along the east coast of Africa and feeds the strong Agulhas current. To the south of latitude 30°S, the Agulhas current is a well-defined and narrow current that extends less than 100 kilometers (62 miles) from the coast. To the south of South Africa, the greatest volume of its waters bends sharply to the south and then toward the east, thus returning to the Indian Ocean by joining the flow from South Africa toward Australia across the southern part of that ocean. However, a small portion of the Agulhas current water appears to round the Cape of Good Hope from the Indian Ocean and continue into the Atlantic Ocean. See also **Ocean Currents**.

AIChE. The American Institute of Chemical Engineers was founded in Philadelphia, Pennsylvania, in 1908 to serve what, at that time, was an emerging new engineering discipline, *chemical engineering*. The general aim of the Institute is to promote excellence in the development and practice of chemical engineering through semiannual district meeting and an annual national meeting for the presentation and discussion of technical papers and the exhibition of equipment and materials used in chemical engineering projects. The Institute publishes several periodicals, including the *AIChE Journal, International Chemical Engineering*, and *Chemical Engineering Progress*. Technical divisions of the AIChE include Computer and Systems Technology, Engineering and Construction Contracting, Environmental Technology, Food, Pharmaceutical and Bioengineering, Forest Products, Fuels and Petrochemicals, Heat Transfer and Energy Conversion, Management, Materials Engineering and Sciences, Nuclear Engineering, Safety and Health, and Separations Technology. The Institute sponsors research projects in cooperation with corporate, governmental, and institutional sources, including the Center for Chemical Process Safety (CCPS), the Center for Waste Reduction Technologies (CWRT), the Design Institute for Emergency Relief Systems (DIERS), the Design Institute for Physical Property Data (DIPRR), the Process Data Exchange Institute (PDXI), and the Research Institute for Food Engineering. Headquarters of the AIChE is in New York City.

AIDS. See **Acquired Immune Deficiency Syndrome (AIDS)**; and **Immune System and Immunology**.

AIDS-RELATED EYE DISORDERS. Acquired Immunodeficiency Syndrome (AIDS) is a disease caused by the human immunodeficiency virus (HIV) that attacks T-cells. These lymphocytes, or white blood cells, are essential to the body's immune defense syndrome.

Infection with HIV does not immediately result in AIDS, but most infected persons develop the disease over a period of years. About 70% of HIV-infected individuals develop AIDS within 15 years.

The gradual deterioration of the immune system leaves the HIV-infected person vulnerable to damage from microorganisms that the body ordinarily handles with ease. There are many effects on the eyes.

There are a number of eye-related symptoms caused by AIDS:

Cotton wool spots—a consequence of bleeding and white spots in the retina, resulting from inflammation of the blood vessels of the retina. Cotton wool spots, named after their appearance, are not dangerous and often disappear in a matter of weeks.

Red eye—infections that last for a long time and cause reddening of the eyes.

Kaposi's sarcoma—a noncancerous tumor that can appear on any part of the body, including the eyes. In the eye, a Kaposi's sarcoma appears as a purple-red bump on the eyelid or a spot on the sclera, the white of the eye. This growth can be treated with radiation, laser therapy, or the freezing treatment called cryotherapy.

Herpes, toxoplasmosis, and zoster—eye infections that are common in AIDS patients.

CMV retinitis—an infection caused by the cytomegalovirus. It is the most serious AIDS-related eye disorder. This retinitis can occur in as many as 30% of AIDS patients and is more prevalent as the disease progresses and the number of protective T-cells declines. The symptoms of CMV infection include floating spots, or "spider webs," flashing lights, blind spots, and blurred vision. Any of these symptoms should be brought to the attention of a doctor immediately. But CMV retinitis can also occur without such symptoms, so it is important for anyone with AIDS to have regular eye examinations, because the disease can cause permanent eye damage.

CMV infection is commonly treated with two drugs, Ganciclovir and Foscarnet. These drugs slow the progress of the disease but do not eliminate it. If only one eye is infected with CMV, drug treatment can prevent infection of the other eye. The drugs used to treat CMV infection are expensive, costing $50,000 or more a year per patient, and they must be taken indefinitely.

Results of a 1999 study by the National Eye Institute offer hope for some AIDS patients with CMV retinitis. The study found that a cocktail of drugs called HAART, an acronym for highly active antiretroviral therapy, can rejuvenate the immune system to the point where some patients can stop taking anti-CMV medications and their CMV retinitis does not become worse. The study tracked 14 patients with CMV retinitis taking HAART. After two years of not taking standard anti-CMV medications, none of patients showed any progression of their retinitis. Some patients did experience uveitis and eye inflammation, as the immune system became more powerful under HAART treatment. See also **Uveitis**.

Although HIV can be found in tears, as well as in all other body fluids, it cannot be transmitted by contact with tears of an infected person. HIV infection is contracted only by close personal contact — having unprotected sex with an infected person, sharing hypodermic needles, getting a transfusion of virus-carrying blood, or being born to a mother infected with HIV. Nevertheless, ophthalmologists and other physicians who treat HIV-infected persons keep all instruments and surfaces sterile and disinfected. Diagnostic contact lenses are cleaned to kill any HIV and prevent transmission of the infection. See also **Acquired Immune Deficiency Syndrome (AIDS)**.

Vision Rx, Inc., Elmsford, NY

AILERON. The aileron is one of the three aerodynamic surfaces of an airplane which are variable in position at the will of the pilot, the purpose of which is to provide the required degree of maneuverability and control of the aircraft about its longitudinal axis. The aileron is that surface which causes the necessary forces to be produced to induce rotation of the aircraft.

This motion is known as *roll*, which is employed to correct other rolls produced unintentionally, as by gusts — when not used to accomplish such maneuvers as banks or sideslips.

The conventional type of aileron is a flap inserted in the trailing edge of the wing, usually at the tip. This flap can be rotated around its forward axis, upward and downward, and in effect changes the camber of the airfoil. The result is a change of pressure on that portion of the wing over which the aileron extends. The change in pressure is greater on the side where the aileron is rotated downward and less on the side where it is rotated upward. The difference in pressure causes the airplane to roll. When the airplane has reached the required angle of bank, the ailerons are returned to neutral. The ailerons are then used in the opposite direction to bring the airplane to its level or normal position, when again the ailerons are returned to neutral. The principal defect of the flap-type aileron is that it becomes relatively ineffective when, for safety's sake, it is needed to be most effective, i.e., when the airplane approaches the stall, or is stalled. (This stall situation refers to the aerodynamic stall of the wing, not to the stall of the engine.) With adequate control of roll during a stall, many serious accidents involving tailspin can be avoided. This defect can be minimized by careful design, and avoided by proper handling of the aircraft. The flap-type ailerons produce some adverse yawing moments, in addition to the desirable rolling moments. This yawing moment is counteracted by use of the rudders.

The aerodynamic efficiency, simplicity, and reliability of the flap-type aileron are better than for other types, such as wing-tip ailerons and spoiler ailerons. See also **Aerodynamics and Aerostatics**.

AIR. In addition to being the principal substance of the earth's atmosphere, air is a major industrial medium and chemical raw material. The average composition of dry air at sea level, disregarding unusual concentrations of certain pollutants, is given in Table 1. The amount of water vapor in the air varies seasonally and geographically and is a factor of large importance where air in stoichiometric quantities is required for reaction processes, or where water vapor must be removed in air-conditioning and compressed-air systems. The water content of air for varying conditions of temperature and pressure is shown in Table 2. The water content of saturated air at various temperatures is shown in Fig. 1. See also **Oxygen**; **Nitrogen**; and **Pollution (Air)**.

TABLE 1. COMPOSITION OF AIR

Constituent	Percent by Weight	Percent by Volume
Oxygen (O_2)	23.15	20.95
Ozone (O_3)	1.7×10^{-6}	0.00005
Nitrogen (N_2)	75.54	78.08
Carbon dioxide (CO_2)	0.05	0.03
Argon (Ar)	1.26	0.93
Neon (Ne)	0.0012	0.0018
Krypton (Kr)	0.0003	0.0001
Helium (He)	0.00007	0.0005
Xenon (Xe)	5.6×10^{-5}	0.000008
Hydrogen (H_2)	0.000004	0.00005
Methane (CH_4)	trace	trace
Nitrous oxide (N_2O)	trace	trace

TABLE 2. WATER CONTENT OF SATURATED AIR

Temperature		Water Content (Pounds in 1 Pound of Air, or Kilograms in 1 Kilogram of Air)
(°F)	(°C)	
40	4.44	0.00520
45	7.22	0.00632
50	10	0.00765

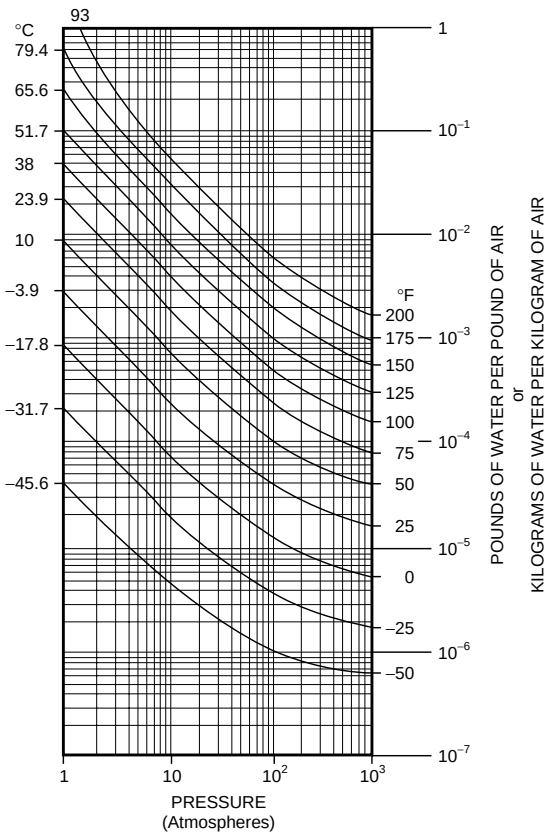

Fig. 1. Water content of saturated air at various temperatures and pressures.

AIRBORNE PARTICULATES. Solid particles suspended in the air. Larger particles (>100 μm approximately) have terminal velocities greater than about 0.5 $m\,s^{-1}$ and fall out quickly. These include hail, snow, graupel, insect debris, room dust, soot aggregates, coarse sand, gravel, and sea spray. Medium-size particles (1 to 100 μm approximately) have sedimentation velocities greater than 0.2 $m\,h^{-1}$ and settle out slowly. These include fine ice crystals, pollen, hair, large bacteria, windblown dust, fly ash, coal dust, silt, fine sand, and small dust. Small particles (>1 μm, approximately) fall so slowly that they can take days to years to settle out of a quiescent atmosphere. For a turbulent atmosphere they may never fall out; however, they can be washed out by rain in a process called *rainout* or *washout*, leading to wet deposition onto the earth's surface. Examples of these particles include viruses, small bacteria, metallurgical fumes, soot, oil smoke, tobacco smoke, clay, and fumes. Oil and tobacco smoke are sticky, and are removed from the atmosphere when they happen to touch and stick to an object such as plant or house furnishings, in a process called *dry deposition*. See also **Deposition**; and **Pollution (Air)**.

AIRBORNE WEATHER RADAR. Radar equipment mounted on an aircraft for purposes of weather avoidance or weather observation. Airborne weather avoidance radars are typically mounted in the nose of the aircraft, scanning ahead of the aircraft for weather hazards. Airborne research radars are frequently Doppler radars that provide measurements of radial wind or turbulence in addition to radar reflectivity. These radars are typically side-pointing or helical scanning and may use dual beams to enable dual- Doppler analysis of storm motions. Airborne weather radars ordinarily operate at wavelengths of C-band or shorter to keep the physical size of the equipment small. See also **Radar**.

AIR COMPRESSION AND COMPRESSION OF OTHER GASES. The compression of air by mechanical means, and the raising of it to some desired pressure above that of the atmosphere, is effected, usually, by an approximate adiabatic change of state.

If ideal compression were possible, it would be represented by the following equation showing the relation between pressure and volume:

$$PV^{1.4} = \text{a constant}$$

A compression of this nature may heat the air to temperatures that would interfere with reliable action of an air compressor and introduce lubrication difficulties, were there no provision for cooling the cylinder walls. Therefore, in compressors we find the cylinders to be externally finned or water-jacketed so that sufficient cooling is secured to keep the temperatures from becoming excessive. The extraction of heat from the cycle in this way modifies the conditions of compression from the ideal to some change more nearly represented by

$$PV^n = C$$

in which n usually lies between 1.35 and 1.4. The ratio of the temperature before and after compression is expressed by the following equation, the temperatures being degrees Fahrenheit absolute.

$$\frac{T_2}{T_1} = \left[\frac{V_1}{V_2}\right]^{n-1}$$

In compression to high pressures, the temperature rise may be too great to permit the compression to be carried to completion in one cylinder, even though it is cooled as mentioned above. In high-pressure compressors, the compression is carried out in stages, with a partial increase of the pressure in each stage, and cooling of the air between the stages. Two- and three-stage compression is very common where pressures of 300–1000 lbs. per sq. in. (20–68 atmospheres) are needed.

The volume of clearance air should be made as small as possible in order to improve the volumetric efficiency of the compressor, since the clearance air must expand to the suction pressure before the cylinder can begin to be charged.

The mechanical construction of air compressors varies with the amount of compression required and the character of service.

Air Compressors. Mechanical air compressors can be classified into two major groups: (1) *reciprocating compressors* of the piston-and-cylinder type; and (2) *rotating compressors*, which may be further divided into a number of kinds. Since the reciprocating compressors were the earliest type to be developed, at any rate for higher pressors, they are discussed first in this entry.

Reciprocating Compressors. A common type of air compressor is the piston and cylinder compressor in which a reciprocating piston positively displaces the air from a cylinder during its discharge stroke. Compressors for charging tanks of air used to inflate pneumatic tires at the numerous automotive service stations are of the reciprocating type. Being of small capacity they are generally single acting and air cooled (by exterior fins) since those features are common in small compressors. Larger compressors, unless for extremely high pressure, are usually double acting and frequently cooled by water jackets. One or two cylinder arrangements are conventional, with a tendency to secure large capacity by increased bore and stroke rather than by multiple cylinders. Pistons are reciprocated by a crankshaft and connecting rod mechanism commonly deriving motion from the driving source by belt. Valves are spring-loaded to open upon slight differential pressures.

The compressor cycle is shown in Fig. 1. The discharge stroke which begins at A builds up the pressure to B where it exceeds the receiver pressure sufficiently to open a discharge valve. Discharge then takes place at a constant control pressure from B to C. The volume C is the clearance volume of the compressor. The air in the clearance volume must expand to D during the suction stroke before the inlet valve will open. Thus the volume of air drawn in per stroke is only that from D to A. Obviously the compressor should have as small a clearance as possible in order to obtain good volumetric efficiency, especially at high discharge pressures. Small compressors may be operated with high compression ratios (8–12) if desired because cooling is more effective in small cylinders and mechanical strength is readily provided. Large volumes compressed to ratios exceeding 4 will need a multi-stage compressor to permit cooling between stages and to lessen the structural loads on the large first stage cylinders.

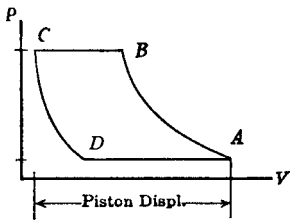

Fig. 1. Reciprocating compressor cycle.

Rotating compressors. may be classified into four types ranging from the (1) centrifugal and (2) axial compressors that are often used for high pressure service to (3) blowers and (4) fans used for low pressure — large volume operation. Since, however, the term compressor is so often restricted to higher pressure service, blowers and fans are treated in separate entries in this book, leaving this one to deal with centrifugal and axial flow compressors.

Centrifugal Compressors. A rotating impeller mounted in a casing and revolved at high speed will cause a fluid that is continuously admitted near the center of rotation to experience an outward flow and a pressure rise due to centrifugal action.

Assume that an impeller with radial blades of depth $r_2 - r_1$ is revolving at a speed of ω radians per minute. This is illustrated in Fig. 2. Consider that a compressible fluid (a gas) is admitted at the center and flows into the impeller radially. Relative to the impeller blades it has an outward

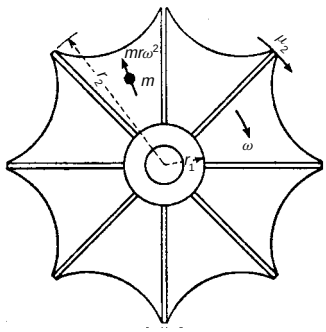

Fig. 2. Impeller for centrifugal compressor.

radial flow, finally emerging with some absolute velocity v_2 which is partially diffused into pressure. In addition a pressure gradient must exist to balance the sum of all the incremental $mr\omega^2$ inertia forces arising from the inward acceleration $r\omega^2$ given each particle of the fluid. The interrelation of r, ω, P, can readily be developed by considering the power required as (1) that necessary for the thermodynamics of compression, and (2) that which would account for the action of the impeller in effecting certain momentum changes on the fluid.

Without detailing the algebraic procedure, it may be stated that the ability of an impeller to raise the fluid pressure is expressed by the ratio of discharge to inlet pressure, i.e., P_2/P_1

$$\frac{P_2}{P_1} = \left[1 + \frac{\eta z u_2^2}{gRT_1}\right]^{1/z}$$

$$g = 32.2$$

$R = 53.4$ for air
$z =$ a gas coefficient, about 0.286 for air
$T_1 =$ energy coefficient. This would be 1.0 if the flow through the impeller were non-turbulent and frictionless. Typically, $\eta = .75$ to .85.
$u_2 =$ impeller rim velocity, fit per sec.

For pressure ratios higher than can be obtained from the action defined above, several impellers may be mounted on the same shaft and enclosed in a compound casing with passages arranged to lead the output from one impeller to the "eye" of the next. This multi-staging principle is used to produce pressures above the capability of a single impeller compressor. Multi-stage compression may have cooling between the stages so the overall compression may be more isothermal than adiabatic. If compression were isothermal

$$\frac{P_2'}{P_1} = e^{\eta u 2/gRT}$$

Axial-flow Compressors. Figure 3 illustrates the compressing action in an axial-flow multistage compressor. Air flows over a set of stationary airfoils (arranged circumferentially as fixed blading) with an angle of attack α. As the airfoil aspect ratio is small, the downwash created is considerable. Downwash turns the air stream through angle ϵ, which results in a flow channel of increasing cross section. The diffusion thus effected slows down the air velocity to V_2 and increases pressure. The moving airfoils (rotor blades) receive this air stream at V_3 as a result of the vectorial combination of air stream velocity V_2 and blade speed U. Relative to the moving airfoils the downwash again causes a diffusion of velocity and another increase of pressure. The relative velocity V_4 leaving the moving blades produces an absolute final velocity of V_5 because of blade motion. Suitable combinations of U and α enable V_5 to duplicate V_1 and permit a similar following stage. The blade height in the following stage is decreased because of the smaller specific volume of the compressed air. Increasing α will increase the pressure rise without much decrease in volume. The axial-flow compressor should be designed for conservative α's for two reasons. First, an operation near the stalling angle would be hazardous as small variations of α might occur which could burble the airfoils and cause an unstable, rough, or even hazardous condition to exist. Secondly, axial-flow compressors may be employed under conditions where utmost efficiency is imperative (as in gas turbine power units) and α should create the optimum favorable balance between good downwash and minimum turbulent airfoil wake. Axial-flow compressors have been built with energy efficiencies as high as 90%. They may be operated effectively at high speeds, i.e., 5000–50,000 rpm.

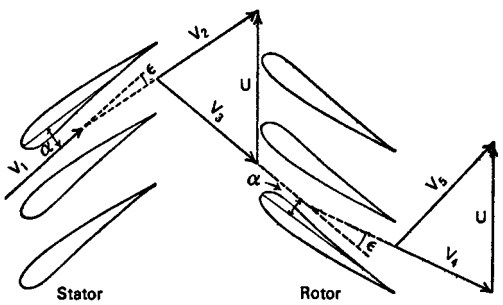

Fig. 3. Velocity relations in axial-flow compressing blading.

The compression of air and other gases may also be secured by the employment of steam jets if an admixture of vapor in the compressed gas is not undesirable. High-pressure steam is blown through nozzles that create a high-velocity jet. The gas to be compressed is led into the regions about the nozzle discharge where it is entrained in the steam jet. The mixture then travels into a diffuser for compression and attendant velocity reduction. Although the compression thus achieved is of limited magnitude, staging the compression in a series of nozzles, with intermediate coolers for partial condensation of vapor, allows moderate compression ratios to be achieved. See also **Gas and Expansion Turbines**.

Screw Compressors. Although invented in the 1930s, the oil-injected screw compressor was not considered seriously by the oil and chemical industries until the 1960s. Today, screw compressors are used widely in refrigeration and natural gas compression. These compressors are oil-injected helical screw machines that are positive-displacement devices. See Fig. 4. In this compressor, a volume of gas is trapped in a defined space. The volume is reduced with a corresponding pressure increase, as in a reciprocating compressor. As pointed out by B.C. Price (Arco Oil & Gas Co.), "The difference is that this compression action occurs without reciprocating motion and the resulting pulsations. Gas is transported axially through the machine in a continuous flow without pulsations. Compression is accomplished without the need for suction and discharge valves and thus has fewer moving parts."

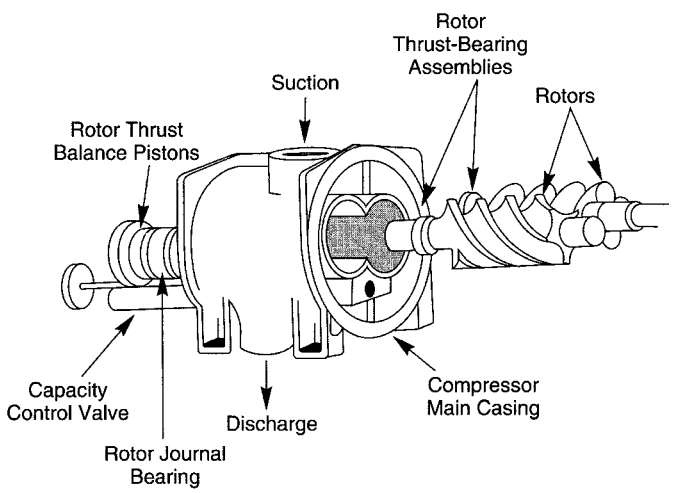

Fig. 4. Schematic of screw-type gas compressor. (*After Price*.)

The screw compressor consists of two rotors enclosed in a pressure-containing casing. The rotors differ in shape and are identified as the "male" and "female" unit. The male rotor has four lobes with an asymmetric profile formed helically along the shaft. These lobes mesh with the six flutes of the female rotor. As the units rotate, gas is drawn through the suction nozzle into the interlobe space. As rotation continues, the rotors mesh to trap the gas and isolate it from the suction. The volume of gas constantly is reduced along its path, with a resulting increase in pressure. While the gas is being moved along axially, the next charge of gas is drawn into the machine and the process is repeated.

Further details on the machine can be found in an article by B.C. Price (*Chemical Eng. Progress*, 50, February 1991).

AIR CONDITIONING. See **Heat Pump**; and **Solar Energy**.

AIRCRAFT CEILING. See **Meteorology**.

AIRCRAFT ELECTRIFICATION. 1. The accumulation of a net electrical charge on the surface of aircraft. 2. Or the separation of charge into two concentrations of opposite sign on distinct portions of the aircraft surface.

Net charges appear as a result of autogenous electrification when aircraft fly through clouds of ice crystals or dust. Charge separation occurs by induction when aircraft fly through regions of strong atmospheric electric field, as in thunderstorms. Charging may also occur by the engine exhaust carrying away a net charge leaving the aircraft charged. Development of large local charges on aircraft parts may lead to appearance of corona discharge or St. Elmo's fire and is almost always accompanied by poor radio communication due to so-called *precipitation static*.

AIRCRAFT ICING. Aircraft flying in airspace that is also occupied by liquid water drops and droplets at temperatures below $0\,^{\circ}$C experience ice accumulation on the leading edges and surfaces of their structures. Water can remain in liquid form to temperatures near $-40\,^{\circ}$C although most clouds tend to be composed of ice crystals in the temperature range of -20, to $-30\,^{\circ}$C or lower. The airspace in which aircraft icing is most commonly encountered lies between the earth's surface and 20,000 feet (6000 meters).

There are several factors involved in aircraft icing. The amount of supercooled water in the space swept out by the moving plane determines in major part the intensity of icing, i.e., the rate of accumulation. The speed of the plane is another factor because at high speeds the plane sweeps out more space in less time. Drop and droplet size has a modifying effect on accumulation. Very small droplets tend to follow the airflow around the plane's surfaces and do not impact to freeze. Large drops like rain tend to abandon the airstream, impact on the plane and freeze. A cloud with large numbers of very small droplets therefore may be much less of a hazard than airspace containing many fewer drops of falling rain.

The temperature of the airspace determines in large part the type of icing. When drops and droplets freeze instantly the water material does not have time to assume a crystalline structure and the ice formation tends to be opaque, often granular with occluded air, usually less dense than clear ice, and frequently an irregular surface. This is *rime ice*. On the other hand, when liquid droplets and drops do have time to crystallize, the ice formation tends to be more or less clear, usually near the density of ordinary ice, and tends to assume the shape of the external aircraft surfaces over which it spreads as it freezes. This is *clear ice*. Temperatures just less than freezing are conducive to clear icing and temperatures well below $0\,^{\circ}$C are associated with rime icing. See Figs. 1 and 2. Aircraft icing is usually a mix of the two types with the proportion of the two related to the temperature.

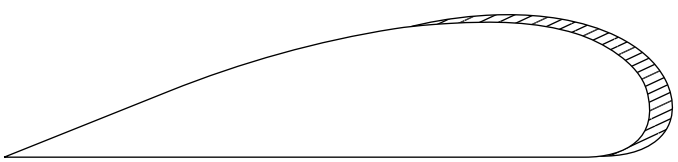

Fig. 1. Rime ice accumulation on the leading edge of a wing tends to be irregular, rough, and a spoiler of the air flow, but is not as heavy as clear ice.

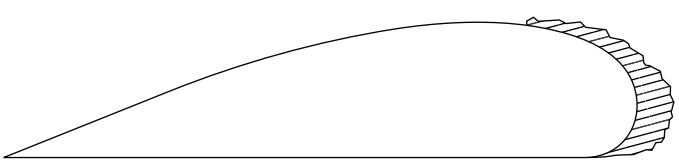

Fig. 2. Clear ice accumulation on the leading edge of a wing tends to be smooth and symmetrical, but heavy.

Clouds most prone to contain an icing hazard are those of cumulo form including billowing stratocumulus. Clouds least prone to contain icing or to contain icing of lesser intensity are stratus. Rain falling from a warm layer of air into a cold lower layer whose temperature is less than $0\,^{\circ}$C is the most intense of all icing conditions. Meteorological arrangements that produce freezing rain or supercooled rain are predominantly along the cold side of warm fronts and secondarily behind cold fronts. Aircraft icing remains a very serious problem.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

AIRCRAFT TURBULENCE. Irregular motion of an aircraft in flight, especially when characterized by rapid up-and-down motion, caused by a rapid variation of atmospheric wind velocities.

This can occur in cloudy areas (particularly towering cumulus and lenticular clouds) and in clear air. Turbulence is the leading cause of nonfatal passenger and flight attendant injuries. The U.S. Federal Aviation Administration (FAA) classifies aircraft turbulence as follows:

- Light: Causes slight, erratic changes in altitude and/or attitude, and rhythmic bumpiness as occupants feel a slight strain against seat belts.
- Moderate: Similar to light, but of greater intensity, with rapid bumps or jolts, and occupants feel a slight strain against seat belts.
- Severe: Turbulence that causes large, abrupt changes in altitude and attitude, and large variations in airspeed, with the aircraft temporarily out of control. Occupants are forced violently against their seat belts and objects are tossed about, with food service and walking impossible.
- Extreme: The aircraft is tossed about so violently that it is practically impossible to control, and structural damage may occur.

See also **Clear-Air Turbulence**.

AIR-EARTH CONDUCTION CURRENT. (Also called *fair-weather current*) that part of the air-earth current contributed by the electrical conduction of the atmosphere itself. It is represented as a downward current in storm-free regions all over the world. The conduction current is the largest portion of the air−earth current, far outweighing the contributions made by the precipitation current and convection current, which are zero in storm-free regions. Its magnitude is approximately 3×10^{-12} amperes (A) m^{-2}, or about 1800 A for the entire earth. Such observations of the vertical variation of the conduction current as have been made indicate that it is approximately uniform throughout the depth of the troposphere, a condition that is consistent with the generally accepted view that the conduction current flows from a positively charged conducting region in the lower ionosphere downward to the negatively charged earth. Only in areas of temporarily disturbed weather does the conduction current become replaced by reverse flow. Accumulating evidence points to the conclusion that the conduction current continues to exist only because of the action of thunderstorms scattered at all times over the earth, which supply the positive charge to the upper atmosphere and negative charge to the earth. See also **Air-Earth Current**; and **Supply Current**.

Additional Reading

Gish, O.H.: "Air-Earth Conduction Current," In *Compendium of Meteorology*, American Meteorological Society, Boston, MA, 1951, p. 113.

AIR-EARTH CURRENT. The transfer of electric charge from the positively charged atmosphere to the negatively charged earth. This current is made up of the air−earth conduction current, a point-discharge current, a precipitation current, a convection current, and miscellaneous smaller contributions. Of these, the air−earth conduction current is by far the largest. This is not just true locally, but throughout the world where there are no thunderstorms occurring, which is estimated to be 80%−90% percent of the earth. The existence of this quasi-steady current in fair weather and the observed maintenance of the earth's net negative charge are both better established than the nature of the supply current, which must replenish the positive charge in the upper atmosphere and the negative charge on the earth. See also **Air-Earth Conduction Current**; **Convection Current**; **Precipitation Current**; and **Supply Current**.

Additional Reading

Gish, O.H.: "Air-Earth Current," in *Compendium of Meteorology*, American Meteorological Society, Boston, MA, 1951, p. 113.

AIRFLOW. A flow or stream of air. An airflow may take place in a wind tunnel, in the induction system of an engine, etc., or a relative airflow can occur, as past the wing or other parts of a moving craft; a rate of flow, measured by mass or volume per unit of time.

AIRFOIL. A structure, piece, or body, originally likened to a foil or leaf in being wide and thin, designed to obtain a useful reaction on itself in its motion through the air.

AIR GAP. This term is commonly used in connection with various magnetic circuits and denotes a gap left in the magnetic material. In the construction of various chokes and transformers used in communications circuits a short gap is usually left in the core material to prevent saturation of the magnetic material by the DC, which often flows in the one or more windings wound on the core material. See **Electromagnet**.

In rotating electrical machinery the rotating part of the magnetic circuit must, of course, be separated by a gap. In these machines this gap is kept as small as is consistent with adequate mechanical clearance. In most instances the gap introduces no desirable electrical or magnetic characteristics and necessitates the application of additional electrical energy to overcome its reluctance.

The term air gap is sometimes used to denote any spark gap, comprising two electrodes separated by a fluid, commonly air.

AIRGLOW. The quasi-steady radiant emission from the upper atmosphere over middle and low latitudes to be distinguished from the sporadic emission of auroras that occur over high latitudes.

Airglow is a photochemical luminescence (or chemiluminescence) arising from chemical reactions in the upper atmosphere. Many of these reactions leave molecules and atoms in excited states from which they can radiate at certain well-defined wavelengths. Emissions from molecular oxygen O_2, atomic oxygen O, sodium Na, and the hydroxyl radical OH are especially prominent, and measurements of airglow intensity by spectrometric techniques have provided a great deal of information about upper-atmospheric dynamics and chemistry. Historically, airglow has referred to visual radiation. Some recent studies use airglow to refer to radiation outside the visual range.

Also called **Light-of-the-night-sky, Night-sky light, Night-sky luminescence** and **Permanent aurora.**

AIR LIFT PUMP. An air lift is a water pumping method whereby water may be raised from a well through the medium of compressed air. The drop pipe in the well is supplied at the bottom with compressed air from a small air pipe, and the effect of mixture of air and water at the bottom of the drop pipe is to bring water to the surface. This is accomplished either by the water acting as pistons, trapping intermediate layers of air, the expansion of which drives the water pistons to the surface; or by the mingling of air and water, forming a mixture that is sufficiently lighter than the undisturbed water in the well so that the mixture rises above the surrounding water. In order for this rise to reach the surface the discharge pipe must be submerged in the water of the well an amount varying from 100–300% of the actual lift. The pumping efficiency of the system is very low, but it is very suitable for handling gritty or corrosive waters.

AIRLIGHT. Light scattered into quasi-horizontal viewing directions by the atmosphere's molecules and small particles (usually excluding fog and raindrops). On clear to partly cloudy days, airlight is dominated by singly scattered sunlight, but it also includes multiply scattered sunlight from clouds, the surface, and the clear sky. A more restrictive definition limits airlight to clear days; a less restrictive one does not limit the elevation angles at which, airlight is seen. As haze concentrations increase, airlight radiances increase near the horizon, although not without limit. Increased airlight reduces a distant object's contrast, thus reducing its visibility. At sufficiently large horizontal optical thicknesses, airlight reduces this contrast below the threshold contrast, and the object is then visually indistinguishable from its surroundings. Airlight and the artistic term aerial perspective are related, since airlight causes the reduced contrast associated with increased distance to an object. Airlight is distinct from airglow that originates in the upper atmosphere.

AIRLIGHT FORMULA. A version of the radiative transfer equation that predicts the luminance due to airlight (L_a) in the direction of a perfectly black object near the horizon. L_a can be used to calculate daytime visual range. For horizon sky luminance L_h, horizontally uniform extinction coefficient σ, and distance x from the observer:

$$L_a = L_b(1 - \exp(-\sigma x)).$$

Also called Koschmieder's law.

AIR LOCK. An air lock is an air-tight compartment in which the air pressure may be regulated to any desired intensity. When workers are required to work in regions where the air pressure is above that of the atmosphere, an air lock must be provided to permit passage of the workers from the open atmosphere to the pressure region. Thus, in the case of caissons, where workers must labor under a high enough pressure to equalize the hydrostatic pressure existing at the bottom of the caisson, or in tunnels where flooding is avoided by forcing compressed air into it at sufficiently high pressures to hold the water back, the air lock is a feature essential to the maintenance of pressure during the admission of workers. Separate air locks are generally provided for materials and spoil removal. In construction work, the air lock is a chamber of sufficient size to hold the number of persons that must be accommodated in it at one time. It is provided with well-braced doors having sealing-type edges and tightening locks. The chamber is equipped with valves for admitting and releasing air and with safety devices to prevent excessive pressures endangering the lives of the occupants. The air lock must have two air-tight doors, one leading to the atmosphere, the other leading to the pressure region. These doors open inward so that the pressure in the air lock tends to tighten them against the frame. To enter a pressure region, a caisson for example, the workers enter the air lock, after which the door leading to the atmosphere is tightly fastened. Compressed air is then slowly admitted until the pressure in the air lock equals that in the caisson, after which the connecting door may be opened without trouble or loss of air from the working chamber. After the workers enter the caisson, the air lock door is tightly closed, after which the air lock may be opened from the outside without affecting conditions within the caisson.

AIR MASS. A very large bulk of air, having properties (temperature, humidity, thermal structure) that vary only slightly, or vary linearly from point to point within the parcel. Air masses range from about 500–5,000 miles (805–8,045 kilometers) in lateral dimensions. They develop over large, relatively homogeneous, geographical areas where air is stagnant for a sufficient period to acquire the characteristics of that region. These regions are either continental or maritime and are known as air-mass source regions. After an air mass begins to move from its source region, it acquires modifying features characteristic of the surface over which it travels. Modification continues until the air mass loses its identity in the general atmospheric circulation. See also **Air Mass Classification**; **Airmass Climatology**; **Airmass Modification**; **Airmass Precipitation**; **Airmass Shower**; and **Airmass Source Region**.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

AIRMASS CLASSIFICATION. A system used to identify and to characterize the different air. A number of systems have been proposed for the classification of air masses, but the Bergeron classification has been the most widely accepted. In this system, air masses are designated first according to the thermal properties of their source regions: tropical (T); polar (P); and less frequently, arctic or antarctic (A). For characterizing the moisture distribution, air masses are distinguished as to continental (c) and maritime (m) source regions. Further classification according to whether the air is cold (k) or warm (w) relative to the surface over which it is moving indicates the low-level stability conditions of the air, the type of modification from below, and is also related to the weather occurring within the air mass. This outline of classification yields the following identifiers for air masses: cTk, cTw, mTk, mTw, cPk, cPw, mPk, mPw, cAk, cAw, mAk, mAw.

Other classification systems introduce further distinction between stable (s) and unstable (u) conditions in upper levels. Some include equatorial (E), monsoon (M), or superior (S) air. Others omit the arctic (A) type and classify all air masses on the basis of polar and tropical air, separated by the polar front.

The major air classification types may be defined as follows:

Tropical air is developed over low latitudes. Maritime tropical air (mT), the principal type, is produced over the tropical and subtropical seas. It is very warm and humid, and is frequently carried pole-ward on the western flanks of the subtropical highs. Continental tropical air (cT) is produced over subtropical arid regions, and is hot and very dry.

Polar air is developed over high latitudes, especially within the subpolar highs. Continental polar air (cP) has low surface temperature, low moisture content, and, especially in its source regions, great stability in the lower

layers. It is shallow in comparison with arctic air. Maritime polar air (mP) initially possesses similar properties to those of continental polar air; but in passing over warmer water, it becomes unstable with a higher moisture content.

Arctic air is developed mostly in winter over arctic surfaces of ice and snow. It is cold aloft and extends to great heights, but the surface temperatures are often higher than those of polar air. For two or three months in summer, arctic air masses are shallow and rapidly lose their characteristics as they move southward.

Antarctic air is developed over the continent of Antarctica. It is generally colder at the surface in all seasons, and at all levels in austral (Southern Hemisphere) autumn and winter, than arctic air.

Continental air is developed over a large land area, and has the basic continental characteristic of relatively low moisture content.

Maritime air is developed over an extensive water surface, and has the basic maritime quality of high moisture content in at least its lower levels.

Equatorial air, according to some classifications, is the air of the doldrums, or the equatorial trough, to be distinguished somewhat vaguely from the tropical air of the trade-wind zones. Tropical air "becomes" equatorial air when the former enters the equatorial zone and stagnates. There is no significant distinction between the physical properties of these two types of air in the lower troposphere.

Superior air is an exceptionally dry mass of air usually found aloft but occasionally reaching the earth's surface during extreme subsidence processes (that is, the descending motion of air in the atmosphere, usually with the implication that the condition extends over a rather broad area). It is often found above tropical maritime air, bounded by the trade-wind. See also **Air Mass**; and **Monsoon**.

For references see entries on **Climate**; and **Meteorology**.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

AIRMASS CLIMATOLOGY. The representation of the climate of a region by the frequency and characteristics of the air masses under which it lies; basically, a type of synoptic climatology.

It is a development of the representation of the weather associated with winds of different directions (thermal wind roses, etc.) by taking account of the source and trajectory of the air, and it gives a more dynamic picture of the climate than do monthly averages. The first detailed study was by E. Dinies (1932). Dinies gave tables of average temperature, humidity, and cloudiness in Germany associated with eight classes of air in winter and summer (Durst, 1951). Similar tables have since been constructed for many parts of the world.

AIRMASS MODIFICATION. The change of characteristics of an air mass as it moves away from its region of origin. For example, maritime air at midlatitudes that originally has high humidity and cool temperatures can be modified as it blows onshore over coastal mountains, where orographic precipitation causes the air to become drier and warmer by the time it reaches the lee side of the mountains. The rate of air mass modification depends on the differences between its original characteristics and those of the new surface over which it flows.

AIRMASS PRECIPITATION. Any precipitation that can be attributed only to moisture and temperature distribution within an air mass when that air is not, at that location, being influenced by a front or by orographic lifting.

The most common form of airmass precipitation is airmass showers; however, a moist but stable air mass may produce drizzle independent of frontal or orographic influences.

AIRMASS SHOWER. Any precipitation that can be attributed only to moisture and temperature distribution within an air mass when that air is not, at that location, being influenced by a front or by orographic lifting.

The most common form of airmass precipitation is airmass showers; however, a moist but stable air mass may produce drizzle independent of frontal or orographic influences.

AIRMASS SOURCE REGION. Region where air masses originate and acquire their horizontal homogeneous properties of temperature and moisture.

Horizontal homogeneity of the air mass is produced by prolonged contact (days to weeks) with the underlying surface. Main source regions are those in which the permanent or semipermanent anticyclones occur. See also **Atmosphere (Earth)**.

AIR PARCEL. An air parcel is an imaginary volume of air to which may be assigned any or all of the basic dynamic and thermodynamic properties of atmospheric air. A parcel is large enough to contain a very great number of molecules, but small enough so that the properties assigned to it are approximately uniform within it and so that its motions with respect to the surrounding atmosphere do not induce marked compensatory movements. It cannot be given precise numerical definition, but a cubic foot of air might fit well into most contexts where air parcels are discussed, particularly those related to static stability. Conceptually, one could imagine that the air inside a hot air balloon is an air parcel. An air parcel has certain properties; heat and moisture are two important ones. With no outside influence, there is no change to the parcel. When heat is added to a parcel, the parcel becomes warmer than the surrounding environment/atmosphere/air, the parcel will rise. Likewise, when it becomes cooler than the surrounding environment, it will sink.

AIRPLANE. The design and construction of a practical, top-performing aircraft is one of the most demanding of engineering feats. Engineers must wrestle constantly to achieve optimal solutions to inherently conflicting factors — such as aircraft speed versus fuel economy, range versus speed, controllability versus complexity, weight versus strength of materials, passenger comfort and cargo handling efficiency versus initial costs, and the list goes on and on. In addition, all such choice decisions must be made without compromising safety. In some engineering fields, such as bridge or dam building, reasonably optimal design decisions have been made with over a century of experience. Although aviation spans nearly a century from the Wright brothers and Kitty Hawk (1903), design experience simply has not been one of linear extrapolation of initial expertise; rather, airplane design trends have been interrupted periodically by radical departures from the past, as exemplified by changing concepts of motive power (jet versus reciprocating engines) and vast improvements in fuels, or by improvements in materials of construction (new metal alloys and composites), or by new findings pertaining to the very fundamentals of aerodynamics, or by the availability of grossly improved instrumentation and control that has fallen out of solid-state physics and electronics. Again, the list could go on and on. Further, the basic function or need for aviation also has changed over the years, notably including the autogyro and later the helicopter, as well as the transformation of an aircraft to an indispensable tool of the military and the employment of aircraft for scientific reconnaissance. Thus, a survey of the history of aircraft design exhibits comparatively short periods of design stability that are punctuated every few years by fundamental changes.

For example, the introduction of large, jet-powered aircraft, such as the DC-10 with its first flight in August 1970, ushered in an era of some stability in passenger- and cargo-carrying aircraft, punctuated by continuing improvements to a fundamental design. This was reflected by the frequent introduction of new model numbers by the principal manufacturers, including McDonnell Douglas and Boeing, as well as a few European aircraft manufacturers. See Figs 1, 2, 3 and 4. The next era in this field commenced in the late 1980s and early 1990s with the introduction by McDonnell Douglas of the MD-11 tri-jet, the MD-11 COMBI, and the Boeing 777.

If past history is any guide, these are the kinds of airplanes that, again with subsequent improved models, will carry the technology well past the year 2000 (most likely to 2020), at which time another new era will commence. With federal support funding very tight as of the mid-1990s, it appeared unlikely that, with the exception of continued research, the hypersonic space plane would be a commercial reality during the first quarter of the twenty-first century.

Some futurists, however, are already forecasting fundamental changes that may affect those commercial aircraft destined for introduction by the year 2025, plus or minus a few years. In terms of airplanes and associated aviation problems of that future period, the following points have been stressed:

Fig. 1. The DC-10 ushered in the aircraft design era of the 1970s. For nearly 25 years, this has been a virtual workhorse of passenger aviation. The first commercial flight took place in August 1970. The DC-10, with many still in use, is powered by three engines ranging in thrust from 40,000 to 53,000 pounds (178 to 236 kN).

The length is approximately 182 feet (55.4 meters), wing span is over 165 feet (50 meters) on some models; the height is just over 58 feet (17.6 meters). Maximum gross weights, depending upon model, range from 440,000 to 572,000 pounds (199,584 to 259,460 kilograms). Maximum number of passengers carried is up to 380 persons, depending on interior arrangement. Depending upon model, the range for a typical mixed class is from approximately 4300 to 6180 miles (6920 to 9940 kilometers). Cruise speed is 510 knots or 587 miles (945 kilometers) per hour.

As of late 1986, over 440 DC-10s and KC-10s had been produced. The KC-10 is an advanced tanker/cargo aircraft, based upon the DC-10 Series 30CF (convertible freighter). The fleet of DC-10s had flown more than 5.3 billion miles (8.5 billion km) worldwide. Fifty airlines operate DC-10s, serving more than 200 cities. Each week, DC-10s made more than 7000 flights, carrying more than 1.1 million passengers. As of September 1986, DC-10s had transported over 605 million passengers. Revenue flying time totaled more than 11.4 mil hours, passenger miles surpassed 842 billion (1355 billion passenger kilometers), and landings, 3.86 million. Statistics compiled as of June 1, 1986 placed the average daily flight utilization for the DC-10 fleet at nearly 9.6 hours; average DC-10 flight duration was 3.39 hours.

During 1986, the average distance flown by a DC-10 on each commercial flight was 1689 statute miles (2718 km). The shortest flight of 45 statute miles (72 km) was flown by United Airlines between Baltimore, Maryland and Washington, DC. The longest nonstop revenue flight was 6995 statute miles (11,251 km) flown by Finnair, between Helsinki, Finland and Tokyo, Japan. (*McDonnell Douglas Corporation.*)

1. Aircraft designers increasingly will be required to concentrate on sociological and market factors in addition to their past concern with the technical performance of an airplane. For example, with the grossly accelerating usage of telecommunications, the need for business travel will be curtailed. Telestaging of individual conferences and even of large group meetings will have a marked effect on business air travel, which has accounted for a substantial percentage of airline revenues. Some futurists forecast that travel for pleasure and other personal and family reasons will comprise the major portion of airline revenues. This change could cause marked alterations in the interior design of an aircraft and include additional facilities for use during flight for attracting these travelers. With this class of passengers, aircraft speed may be de-emphasized (flight duration lengthened). This could be translated into terms of what might be called "air cruises," which, in essence, would create new trade-offs for the aircraft designer. Futurists forecast that, during the second quarter of the 21st century, airliners with a capacity for 2000 passengers will be common. Flying at lower altitudes would be attractive to such passengers.
2. Some futurists forecast a growing demand for much larger cargo-carrying aircraft, citing the increasing acceptance of the "just-in-time" delivery of parts and components for consumption on manufacturing production lines. The existing large growth of air-delivered packages is expected to continue.
3. Forecasters also suggest that airplane designers must become more concerned with the total aviation system. Traditionally, the starting point in an air travel and cargo movement system has commenced with the airplane design per se, requiring that all other aspects of the system be geared to the aircraft. In essence, this spells out more attention to avionics. As pointed out by R.W. Simpson (Professor of Aeronautics and Astronautics, Massachusetts Institute of Technology), *http://web.mit.edu/afs/athena.mit.edu/dept/aeroastro/www/* "Details on many factors, including wind and aircraft speed and direction, will probably be entered automatically into an enormous computer system that will route and reroute air traffic. Combined with a broad-area surveillance system that will likely rely on satellites instead of radar, improved computerization might even permit one or two controllers to handle thousands of flights at one time. Just a couple of people might direct all the air traffic over the North Atlantic."
4. In a systems approach, airplane designers, in addition to designing rapid and efficient passenger and cargo loading and unloading systems into the aircraft, may be called upon to extend their expertise to the total ground ingress and egress system.
5. Some futurists suggest that aircraft noise pollution remains as one of the principal unsolved problems. With the continuing growth of advocacy groups, this is considered a likely area of controversy of increasing magnitude and one that should be addressed more seriously by aircraft designers.
6. Although not directly within the province of the aircraft designer, there are in general numerous aviation problems of serious concern. One of the greatest, of course, is the need for improved air terminals. Considerable progress is occurring in air traffic control, ground systems, and land expansion, but futurists forecast that the situation in the year 2025 will be untenable in terms of capacity. Some experts suggest the construction of large artificial islands to serve as airports for urban complexes located on the seaboard or near inland lakes, such as Cleveland and Chicago. This was pioneered at least a half-century ago with the construction of the Lake Front Airport in Cleveland. However, such islands, filled deltas, and so on immediately conflict with some environmental and ecological concerns. See article on **Wetlands**.

The 1990–1995 Airplane Design Era

The MD-11 (McDonnell Douglas) is designed with two fuselage lengths approximately 18.6 feet (5.66 m) longer than the DC-10 and an MD-11ER (extended range) that is approximately the same length as the DC-10. Three models include a passenger, an all-freighter, and a "combi," which carries passengers and freight on the same deck.

A wide variety of interior choices is available. Seating capacities on the standard airplane range from 276 persons in a three-class arrangement to 405 people in an all-economy configuration. Below deck, the MD-11

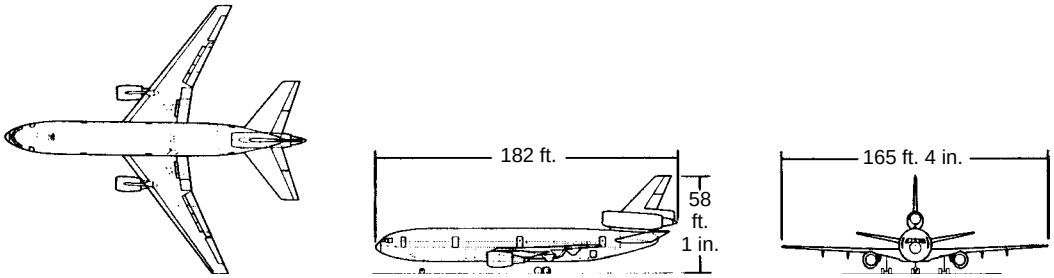

Fig. 2. General arrangement and overall dimensions of the DC-10 Series aircraft. (*McDonnell Douglas Corporation.*)

Fig. 3. Partially assembled DC-10 Series 30 aircraft (at height of production run in early 1980s), showing one of the three large jet engines in foreground being readied for attachment to the aircraft. (*McDonnell Douglas Corporation*.)

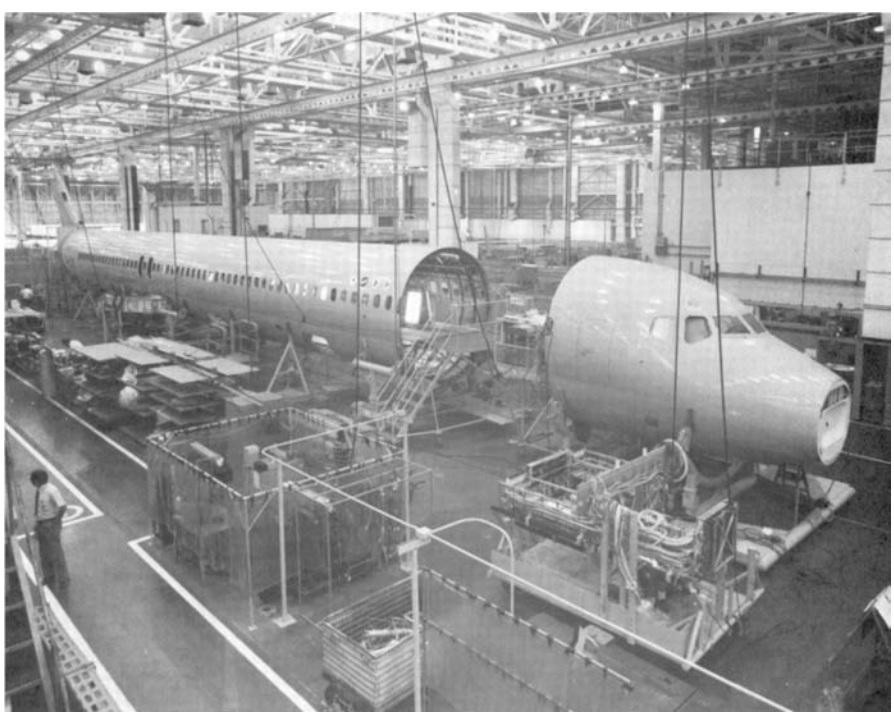

Fig. 4. Partially assembled DC-10 Series 20 aircraft. (*McDonnell Douglas Corporation*.)

provides more combined containerized or pelletized cargo than available aircraft.

Maximum range is up to 7920 statute miles (12,746 km) nonstop, representing an increase of 24% as compared with the DC-10 Series 30 aircraft. A medium-range MD-11, derived from the standard aircraft, has a two-class capacity of 327 passengers and a nonstop range of 4590 miles (8080 km). The extended-range MD-11ER carries 277 first-class and economy passengers and has a nonstop range of 8870 miles (14,274 km), representing a 39% increase in range over the DC-10. See Figs. 5, 6, and 7.

In addition to the numerous engineering and technological features that contribute to the performance and safety of a passenger aircraft, operating economics also are a major consideration and, in essence, determine preferences among the numerous airline purchasers of an aircraft. As of the late 1990s, the market requirements were as follows:

1. *A growing need for new wide-cabin jets*. The availability of used wide-cabin aircraft has dropped by some 85% to a low level. It was predicted that, by 1996, more than 500 of the world's wide-cabin fleet would be over 20 years old.
2. *More passengers, longer routes*. Through 1998, growth of more than 140% was projected for world passenger markets. More growth is seen for long-range direct services. The MD-11 will carry a mixed configuration of 320 passengers more than 6800 nautical miles (12,600 km).

Fig. 5. The MD-11 tri-jet. The design is based upon experience gained from over 25 years of improving the DC-10. The MD-11 features a smaller horizontal tail and winglets (vertical airfoils at the wing tips). Both of these features contribute to improved range by reducing in-flight aerodynamic drag. (*McDonnell Douglas Corporation*.)

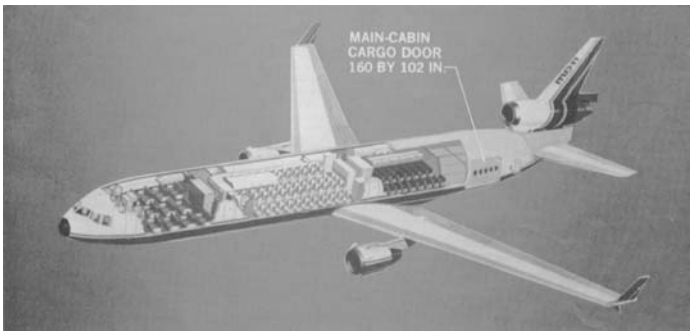

Fig. 6. The MD-11 COMBI provides a combination of passenger and cargo accommodations on the main deck. One design includes first-class and economy seating in the forward and mid-cabins for 214 persons, plus six pallets in the rear cabin. A large cargo door is provided in the aft fuselage. (*McDonnell-Douglas Corporation*.)

3. *Greater cargo capacity*. This market was projected to grow more than 150% by 1998. Numerous older cargo jets were being retired. Consequently, in designing a new aircraft, such as the MD-11, substantially more below-deck revenue-cargo capacity had to be designed into a wide-cabin passenger aircraft. This amounted to an increase of about 40% in the MD-11, as compared with the current DC-10.
4. *More interior flexibility*. The composition of multiclass service varies around the world and is constantly changing, currently in favor of a larger business-class configuration.
5. *Increased performance and profitability*. This requirement affects nearly all aspects of aircraft design and notably the size and power plant configuration. Other factors include more efficient usage of human power required to operate the aircraft and substituting, wherever practical, instrumental and computerized techniques for improving the efficiency of the crew.

In early 1969, Boeing introduced its "jumbo jet" airliner, the first of its 747 series. Over a period of approximately two decades, Boeing added eight different models, most having a gross weight of 836,000 pounds. These included the 747-200B, the 747-300, and a 747-Freighter model. The 747-100 was fitted especially to transport the space shuttle from California to NASA launching headquarters in Florida. The basic 747 aircraft was approximately 232 feet (70.7 m) long.

In the late 1980s, Boeing announced plans to build a 747-400 series of aircraft to enter service by the mid-1990s. The aircraft featured the most advanced digitized avionics available.

Aircraft Instrumentation and Automation

In terms of *total systems* instrumentation, aircraft lagged behind the manufacturing and processing industries in the adaptation of instruments and automation. The very early planes of the pre–World War I era simply utilized a magnetic compass, a barometric altimeter, and an anemometer to indicate airspeed in the cockpit. Between the two World Wars, gyroscopes (vertical and horizontal attitude) and accelerometers (turning indicators) were added to the pilot's panel. Between the mid-1940s and mid-1960s, the pilot was aided by radio altimeters, weather radar, basic alarms for fuel, temperature, and landing-gear status, and analog airspeed and altitude indicators. Between 1965 and 1980, mechanized flight directors for guiding stick, rudder, and other control movements were added. Digital computers were used for the first time to monitor and indicate the status of the hydraulic and electrical systems. During the interim period between 1980 and the present, an array of electronic displays were added, as well as side-stick controllers, moving-map displays, collision avoidance systems, and flight management systems.

Automatic pilots for maintaining speed and direction were not added until the 1950s. During this same period, analog flight stability computers were first used. Automatic landing systems were added during the 1965–1980 period, as were hydraulic systems to assist in moving flight surfaces. Inertial navigation systems also appeared during this period.

Progress from 1980 to the 1990s included so-called "fly by wire" digital computers for actuating flight surfaces over an electric network. In special instances, additions included the global positioning navigation system and a microwave system for guiding an aircraft on a curved approach.

Shown schematically in Fig. 8 is the panel of controls planned for the forthcoming Boeing 747-400 series of aircraft.

Since the concept of an "automatic pilot" first was envisioned, there has been considerable disagreement among experts pertaining to the blending of automation with human factors engineering. Accidents have been attributed to the manner in which pilots have used (or misused)

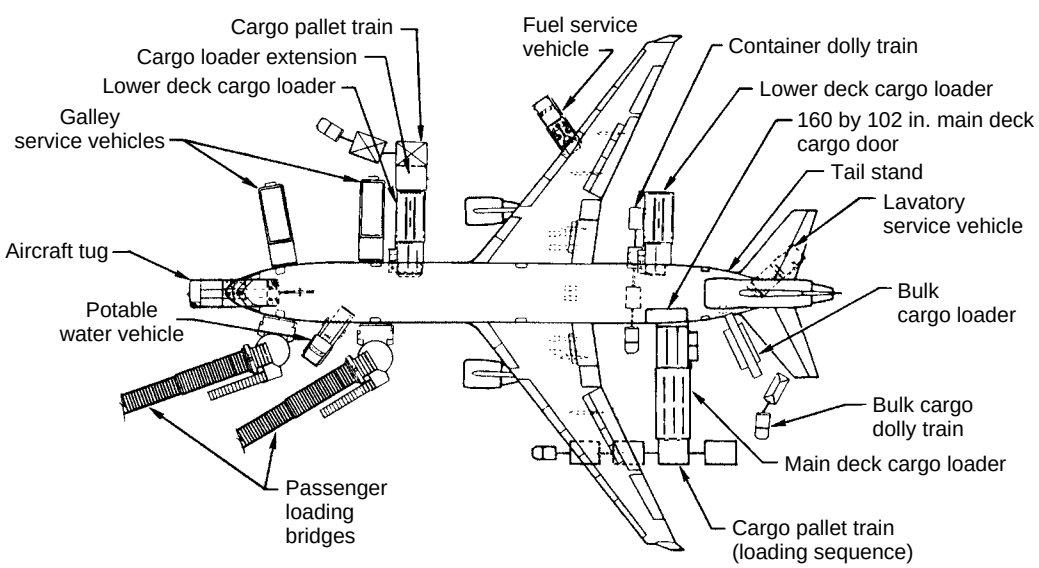

Fig. 7. Ground service equipment arrangement for the MD-11 COMBI. (*McDonnell Douglas Corporation*.)

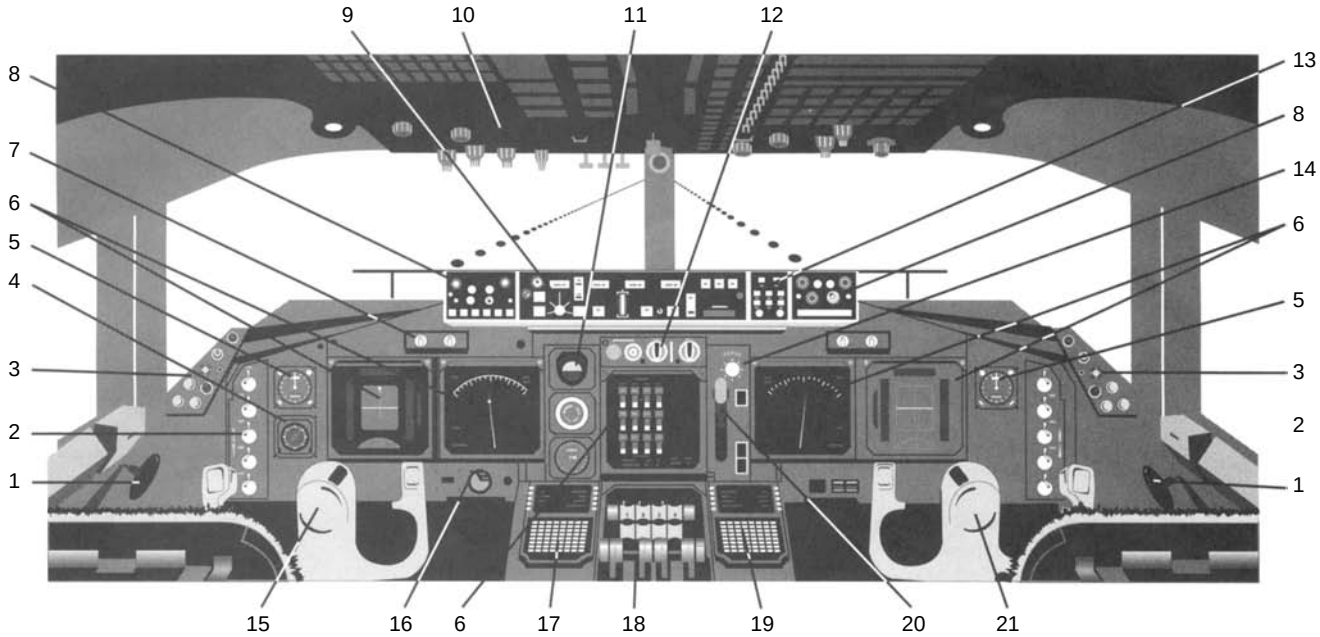

Fig. 8. Instrumentation and automation available to pilots in the Boeing 747-400: (1) nosewheel steering tiller; (2) instrument source selection; (3) internal lighting controls; (4) radio magnetic indicator; (5) real-time clock; (6) electronic flight instrument system; (7) display switching; (8) electronic flight instrument system control panel; (9) autopilot flight director system mode control panel; (10) overhead panel (engine start; electrical system; hydraulic system; oxygen system; fuel system; fire control; inertial navigation; system mode select; and temperature control); (11) standby instruments; (12) electronic flight instrument system control panel; (13) engine indication and crew alert system; (14) alternate flap controls; (15) captain's control column; (16) brake pressure indicator; (17) maintenance control display unit; (18) engine controls; (19) alternate gear controls; (20) landing gear extension handle; and (21) first officer's control column.

an airplane's automatic system. A system study of human factors and aircraft automation is now being undertaken by an interagency National Plan for Aviation Human Factors, coordinated by the Federal Aviation Administration. *http://www.faa.gov/aar/Human-Factors/Welcome.HT*

The revised National Plan completed in 1995, re-emphasizes human performance from a NAS perspective where the system encompasses the broadest interests of the aviation community including flight deck, aircraft cabin, air traffic control, airway facilities, aircraft maintenance, and commercial and general aviation operations, as well as the regulatory and organizational activities affecting these elements. This initiative describes the contributions of NASA, FAA, and DoD, along with structured recommendations from the private sector of the aviation community. It addresses current and future research needs, and required implementation activities arising from discussions within the public and private sectors of the aviation community.

Airplane Design Fundamentals

An airplane may be defined as an aerodynamically designed, winged, powered, heavier-than-air craft intended for sustained flight in the earth's atmosphere. A glider is an engineless airplane. The airplane is part of the total family of aircraft, which includes other heavier-than-air forms, such as helicopters and autogiros, and lighter-than-air forms, such as balloons and airships (blimps, dirigibles, zeppelins).

Various configurations of airplanes serve two major uses: (1) as vehicles for transporting people and goods; and (2) as military weapons systems. Other important uses, although relatively minor in terms of the number of aircraft used, include: (a) as carriers of airborne instruments for collecting geophysical, geodetic, and meteorological information (mapping, surveying, mineral and natural resource exploration, weather observation); (b) as searching tools — for lost persons and craft at sea, in jungles, mountainous terrain, and desert — and for determining the presence of dangerous conditions (forest fires, rising flood waters, hurricane centers, and movement); (c) as airborne inspection and command posts for the supervision and management of geographically sprawling projects (ranching operations, construction projects, such as tunnels, highways, pipelines, commercial fishing operations) — however, these operations are frequently assigned to helicopters; (d) as "dusters" of crops for spreading insecticides and treating chemicals required by certain types of agricultural products; (e) as forest fire fighters, for carrying and dropping water and chemicals; and (f) as subsystems for controlling automotive vehicular traffic and for seeking out and helping in the apprehension of crime suspects — roles also often assigned to helicopters.

Military aircraft fall into three major classifications: (1) for bombing, strafing, and other offensive operations; (2) for fighting enemy aircraft in an effort to attain and maintain control over the air space of a given region — and to intercept enemy bombers and missiles; and (3) for conducting reconnaissance and command operations, including determination of enemy maneuvers and positions, as well as directing land and sea operations from an airborne observation platform. Most other military aircraft are used mainly for transporting people and equipment for numerous purposes.

There are, of course, still other specialized applications for commercial, military, and civil aircraft, not the least of which, in terms of small planes, is their use for recreation and the sport of flying.

With the perfection and refinement of helicopters a few decades ago, some of the former more specialized uses of aircraft have been assumed by the helicopter, with its superior maneuverability and hovering capability as, for example, in rescue missions.

While some valiant efforts were made in the 1800s and even before to obtain some form of sustained flight in a heavier-than-air craft, it is essentially universally accepted that this achievement was first successfully claimed by the Wright brothers of Dayton, Ohio. On December 17, 1903, the Wright brothers made several flights in their wood-and-muslin craft at Kill Devil Hills beach (North Carolina). The first successful flight lasted 12 seconds and traveled 120 feet (36.6 meters). A later flight on the same day was of 59 seconds duration and covered a distance of 852 feet (259.7 meters). Less than two years later (October 5, 1905), in their third major design, the Wright brothers covered a distance of $24\frac{1}{5}$ miles (38.9 kilometers) in a time span of 38 minutes, 3 seconds, at a location called Huffman Prairie, near Dayton.

Although apparently very close to mastering powered flight, Prof. S.P. Langley of the Smithsonian Institution suffered two crashes in his *Aerodrome*, the last crash occurring only nine days prior to the successful flights of the Wright brothers. In the 1890s, the German engineer, Otto Lilienthal, had gained extensive experience with both monoplane and biplane gliders and was at work on motorizing one of his gliders. Unfortunately, he crashed in one of his gliders in 1896.

Propulsion

Following the success of the Wright brothers in developing the first true airplane power plant, engine development progressed rapidly. The Gnome "monosoupape" air-cooled engine of World War I fame was developed in France in 1909. This engine was unique in that the crankcase and cylinders rotated with the propeller about the stationary crankshaft. Good cylinder cooling was obtained by this arrangement, but engine lubrication was a difficult problem. Later in the war, this engine was producing 125 horsepower[1] at 900 revolutions per minute. Major developments by the British and American designers of that period were in liquid-cooled engines. Two famous engines of this type were the 8-cylinder LX 105, which produced 90 horsepower, and the 12-cylinder Liberty engine, which developed up to 400 horsepower. The latter engine was used in a number of different Allied combat airplanes during the latter part of the war and for several years thereafter. The 8-cylinder liquid-cooled Hispano-Suiza engine also powered many World War I airplanes and was the first to incorporate cast aluminum-alloy cylinder blocks with steel liners.

The rate of advancement in aircraft propulsion diminished considerably for a number of years following the close of World War I. However, in the 1930s, the development of the controllable-pitch propeller was a tremendous advance and opened many new possibilities for airplanes of greater weight and speed. The next milestone was the perfection of the gas turbine (jet) engine into a useful airplane power plant. By the end of World War II, reciprocating engines were producing as much as 3500 horsepower and weighed less than one pound per horsepower. This was the peak of development for that type of engine. However, it could no longer compete with the gas-turbine engine which offered far more power output for each pound of installed weight.

Theory of Propulsion. A dynamic flying machine must be set in motion by a force called thrust, provided either by a propeller, the forward component of the lifting force of rotating helicopter wings, the thrust of gas-turbine engine exhaust, or the thrust of rocket engine exhaust. Gliders and soaring machines are initially set in motion by the thrust provided by a launching or towing device. Continued flight is maintained only by descending into rising air currents.

With an airplane, the thrust force must be equal to total airplane drag to maintain level flight at any given speed or altitude. Since airplane drag increases with speed, greater thrust is required for any increase in speed. Thrust force must also be greater than total drag when the airplane is accelerating, as at take-off, or when the airplane is climbing. Generally, an airplane has reached its maximum speed or altitude when all available thrust is being utilized. However, in some high-altitude jet airplanes, the amount of thrust available to meet take-off acceleration and high-altitude climbing requirements is somewhat greater than that required to obtain maximum permissible speeds at lower altitudes because of airframe structural limitations.

In the case of rocket-powered missiles, the thrust is utilized in a somewhat different manner. A large thrust force is used for a short, initial period to gain a very high speed. After the rocket motor has depleted its fuel, the missile continues on its trajectory by means of the energy imparted to it by the high initial thrust. Once outside the earth's atmosphere, space missiles and satellites will continue in motion indefinitely with no friction forces to absorb their energy, until pulled back again by the earth's gravitational field, or "captured" by some other large body in space.

Propellers. The function of a propeller is the conversion of engine shaft torque (turning force) into thrust. In the early days of propeller design, it was thought that thrust was obtained by the rear face of the propeller blade pushing against the air. Later, it was learned that propeller blades should be considered as small rotating airplane wings with the shape of the airfoil being of primary importance. Therefore, the upper surface of the airfoil, or the front rather than the back of the propeller blade, should be given primary design consideration.

Propellers may be installed in two different ways. In the "tractor" installation, the propeller is mounted forward of the wing. The tractor propeller "pulls" the airplane through the air and the thrust bearings in the engine are designed for thrust loads in this direction. Nearly all propeller-driven airplanes are designed for tractor-type installations because of the unrestricted air inflow to the propeller. As the terminology implies, "pusher-type" propellers are installed aft of the wing and push the airplane forward. The first Wright airplane was of the pusher type. The advantage of this arrangement in multi-engine airplanes is that the absence of engine nacelles forward of the wing permits unrestricted airflow over the wing.

Two theories are recognized on the operation of a propeller in converting engine shaft torque to thrust. The momentum theory deals with the energy change to the air mass acted upon by the propeller. The other and most commonly used concept in determining propeller performance is the blade element theory. In this theory (known as the Drzewiecki theory), each propeller blade is considered as being composed of an infinite number of airfoils (called blade elements) joined end to end, forming a shape similar to a twisted airplane wing. Because the propeller is rotating about the engine shaft centerline, each blade element will be rotating in a different arc. The greater the distance of each blade element from the shaft centerline, the larger is the arc it circumscribes and thus the greater the distance it must travel for each revolution. Each blade element, therefore, is moving at a different velocity, which is greatest at the blade tip. If each blade element is to operate at maximum L/D (lift/drag), the angle of attack α for each element must diminish as the distance from the hub increases. This gradual decrease in blade angle gives the propeller blade its twisted appearance.

Since the circumference of a circle is $2\pi r$, each blade element rotates through a circular path of $2\pi r$ during each revolution, with r the distance from the center of rotation, expressed in feet or meters. If the propeller is turning at n revolutions per second, the linear velocity of each blade element in its individual plane of rotation must be $2\pi rn$ feet (meters) per second. In flight, the propeller is moving forward at the same speed as the airplane, as well as rotating about its own axis. This forward velocity must also be expressed in feet (meters) per second to keep all terms of the equation in common dimensions. The total velocity of each blade element is the resultant of the two component velocities, the forward velocity V and the rotational velocity $2\pi rn$, or $2\pi rnV$. This is shown graphically in Fig. 9 for each blade element.

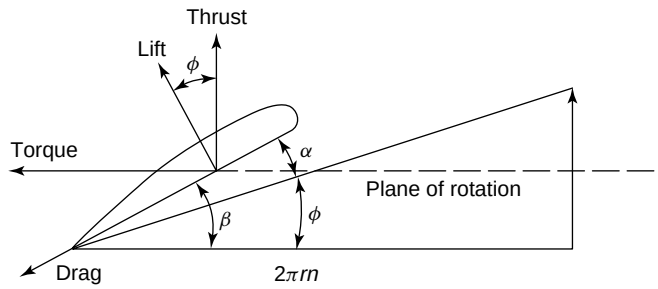

Fig. 9. Vector diagram of propeller blade element.

As shown on the diagram, the angle of attack α is equal to the fixed blade setting angle β, minus the angle ϕ which is determined by airplane velocity V and propeller rotational velocity $2\pi rn$ (or πdn since diameter $= 2r$).

The flow of air about the propeller blade creates lift and drag forces in the same manner as airflow about an airplane wing. The resultant of these forces can be divided into two components, the thrust component acting in the direction of the propeller axis and the torque component. The torque component acting in the plane of rotation resists the operation of the propeller and is the component that must be overcome by the engine shaft torque. Similar to the airplane wing, the magnitude of the thrust and torque components depends upon angle of attack and velocity.

The efficiency of a propeller in converting engine power to thrust is obviously of tremendous importance to airplane performance. The efficiency of a propeller during cruising flight determines the range of an airplane equally as much as the efficiency of the engine itself in converting fuel energy to shaft power. Propeller efficiency is expressed as the ratio of thrust power delivered to engine power required to turn the propeller. Thrust power is thrust force (pounds) multiplied by airplane velocity V (feet per second), or TV (foot-pound/second). The power required to turn the propeller may also be expressed in foot-pound/second by multiplying engine shaft horsepower by 550 since one horsepower is 550 foot-pounds/second.[2] The airspeed at which maximum efficiency occurs is called the design airspeed for the propeller.

[1] One horsepower = 1.014 metric horsepower.

[2] One metric horsepower = 542.5 foot-pounds/second.

Employing fixed-pitch propellers in high-performance airplane design presents numerous problems. If a wing airfoil section is chosen for a transport airplane that will result in maximum L/D at high cruising speeds, a propeller of relatively high angle must also be chosen to yield good efficiency at high cruising speed. However, this propeller will give poor high-speed performance as well as inferior performance at take-off and climb. A high-speed propeller chosen for a high-speed airplane will have reduced efficiency during cruising and give less than optimum range for the airplane, in addition to reduced climb and take-off performance.

The advent of the controllable-pitch propeller offered a solution to these difficulties. Provided with a means for varying pitch angle, the pilot could select the optimum angle for take-off, climb, efficient cruising, or high-speed flight. It is notable to observe that modern propeller airplane performance essentially commenced with the development of the controllable-pitch propeller. Fixed-pitch propellers are used only on small, light airplanes where cost and lightness of installation are major considerations. The speed range of such airplanes is limited by power output of the engine as well as the propeller.

The velocity of the blade elements has little effect on efficiency until velocities near the speed of sound are approached. When the velocity of the blade elements close to the tip approaches the speed of sound, the effect of compressibility increases power input requirements at no increase in thrust, thereby reducing efficiency. Since compressibility of an airfoil is affected by airfoil thickness ratio, propeller tips are built as thin as possible. Speed of sound is proportional to temperature and, normally, tip speed is limited to 800 to 1,000 feet per second (244 to 305 meters/second). To prevent tip speeds from exceeding these limitations, high-powered engines, requiring propellers of large diameter, are equipped with reduction gears. This arrangement permits lower propeller rpm than the engine rpm required for efficient engine power output.

In addition to providing efficient thrust during cruising conditions, the propeller must be able to convert total engine power to thrust for take-off. This is necessary to provide rapid acceleration to flying speed and keep take-off distances within reasonable limits.

Some important propeller terms include:

Fixed-pitch Propeller — A propeller with blade angle fixed.

Adjustable-pitch Propeller — A propeller on which blade angles can be adjusted on the ground with propellers not turning. This is especially convenient for a take-off on a hot day from a high-altitude airport.

Controllable-pitch Propeller — A propeller on which the blade angle may be changed in flight by controls in the cockpit.

Constant-speed Propeller — A controllable-pitch propeller with a speed governor which maintains selected rpm constant by automatically changing blade angle regardless of airspeed or engine power. Most propellers of this type also provide for full "feathering" of the blades in flight to prevent "autorotation" or "windmilling" of the propeller, thus reducing drag when the engine is dead.

Feathering — Mechanically increasing pitch angle until the blade is turned approximately to the direction of flight. Feathering is used most frequently on multiengine airplanes.

Reverse Thrust — Thrust in the direction opposite to flight. Nearly all multiengine airplanes utilize constant-speed, full-feathering, reversible-pitch propellers. The pitch change mechanism is designed to permit the pilot to select negative blade angles immediately after landing, thus creating reverse thrust for rapid airplane deceleration. This feature saves brakes on heavy airplanes and permits safe landings on icy runways where wheel braking is quite ineffective.

Dual Rotation — Two propellers on the same engine shaft and operating in opposite direction. One propeller shaft rotates inside the other while both are driven by reduction gears in the engine nose case.

Windmilling Drag — Perhaps the most undesirable action in the use of propellers as a thrust-producing device is the drag that results from propeller windmilling. If engine power is lost in flight, the airflow over the propeller blades will cause the propellers to rotate and, in turn, rotate the engine. When the blade angle is great enough to be commensurate with the flying speed, propeller efficiency will remain high and the drag will not be appreciably greater than engine load. However, if a failure occurs in the pitch-change mechanism and the blade angle is reduced, excessively high rotational speeds may result. The low blade angle and the resultant negative angle of attack of the blade airfoil element cause a tremendous reduction in propeller efficiency. This means the load required to turn the dead engine is supplied by an inefficient propeller, and the resulting windmilling drag can become dangerously high. In such instances, it is necessary to reduce airspeed or altitude to reduce propeller rotational speed. However, unless actual failure occurs to the pitch-change mechanism, the propeller speed governor will maintain rpm as it was before engine failure, and the feathering system will feather the propeller to stop windmilling rotation altogether. See also **Aerodynamics and Aerostatics**; and **Helicopters and V/STOL Craft**.

Jet Propulsion. The jet or rocket engine moves the airplane or missile forward by reacting to the momentum of a mass of air or gaseous matter accelerating out the rear (nozzle) of the engine. The recoil of a rifle and the reactive thrust of a fire hose are typical examples of this principle. The thrust force is not the result of the jet gases pushing against the air behind, but instead is the reaction to the momentum of the escaping gases. This fact is demonstrated by rocket motors, which produce full thrust in outer space beyond the atmosphere.

Power Measurement. Jet thrust force is measured in pounds as is the thrust force of a propeller. The magnitude of jet gross thrust force is determined by the mass flow of air or gaseous matter multiplied by the velocity with which it escapes from the nozzle. This may be expressed by

$$F = MV_j \tag{1}$$

where F = thrust force, pounds
M = mass flow rate = W/g
V_j = jet velocity, feet per second
W = weight flow, pounds/second
g = gravitational acceleration + 32.2 feet/(second)^2 [9.8 meters/(second)^2]

Because aerodynamic equations require thrust to be expressed as a force, to equate thrust requirements against drag and acceleration forces, there usually is no reason to express jet engine output in terms of horsepower. But, where the equivalent is desired, jet engine "power" can be determined by multiplying thrust force times flying speed in feet per second and dividing by the horsepower constant.

$$\text{Horsepower} = \frac{(\text{Jet Thrust}) \times (\text{True Airspeed}) \times 1.467}{550} \tag{2}$$

Therefore, when flying speed is 550 feet per second (375 miles (603 kilometers) per hour), the jet thrust and jet "power" are the same. At speeds below this value, jet "power" is less than jet thrust in pounds. In the case of the turboprop engine, where both propeller thrust and jet thrust are utilized, it is sometimes desirable to convert jet thrust into horsepower. By adding this value to the horsepower rating of the engine, the total propulsive output of the engine can be expressed as "equivalent shaft horsepower" (eshp). Jet horsepower must be multiplied by propeller efficiency to convert to shaft horsepower. Assuming a propeller efficiency of 80%.

$$\text{eshp} = \frac{(\text{Jet Thrust}) \times (\text{True Airspeed}) \times 1.467 \times 0.80}{550} + \text{Shaft Horsepower} \tag{3}$$

Propulsive Efficiency. The efficiency with which a propulsive system is utilized in propelling the airplane or missile is called propulsive efficiency. A thorough understanding and investigation of propulsive efficiency are necessary for successful design when comparing one propulsion system with another. This is especially true when comparing propeller propulsion with jet propulsion.

Propulsive efficiency may be expressed by

$$\text{Efficiency} = 2V_a/(V_J + V_a) \tag{4}$$

where V_a = airplane velocity, feet per second
V_J = jet velocity (or propeller slipstream velocity), feet per second

In the case of propeller-driven airplanes, propulsive efficiency very closely approximates propeller efficiency because the propeller moves a large mass of air at relatively slow speeds. During cruising conditions, the air behind the propeller is moving at approximately the same speed as the airplane; hence, V_a and V_J are approximately equal. In contrast, the thrust-producing gases escaping from the jet engine nozzle are extremely high in velocity, relatively smaller in mass flow, and cannot be varied extensively in flight.

Because it is difficult to design a pure jet engine that would have satisfactory fuel economy and light weight without high jet velocity, jet-powered airplanes are generally designed for high-speed flight to obtain maximum propulsive efficiency.

High-altitude operation must be considered in propulsive efficiency analysis. Because of compressibility effects on the propeller airfoil, propeller efficiency decreases with both airspeed and altitude. This factor limits propellers to approximately 500 to 600 miles (805 to 965 kilometers) per hour true airspeed and 40,000 to 45,000 feet (12.192 to 13.716 meters) altitude. In contrast, since jet thrust is accomplished at high jet velocities, the higher the airplane speed, the greater is the propulsive efficiency. A comparison of propulsive efficiency for the various propulsion methods is given in Fig. 10.

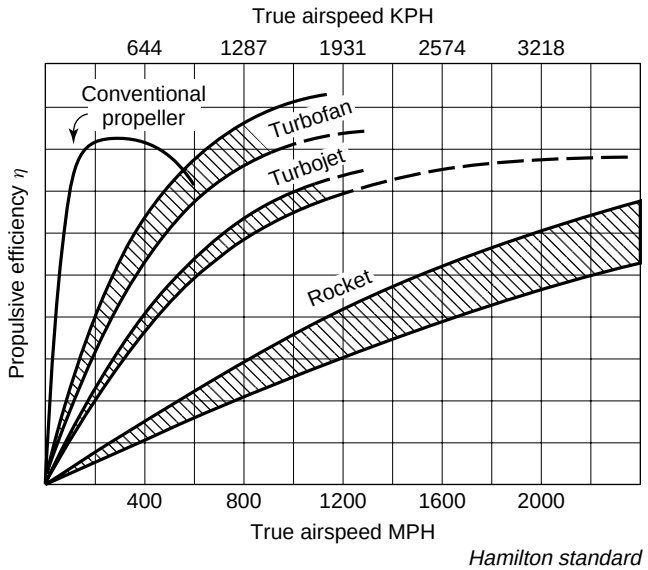

Fig. 10. Comparison of propulsive efficiency.

Turbojet Engines. The principle of jet propulsion was recognized early in aviation development as possibly the best method for obtaining greater speeds. The practical application of the principle proved difficult, however, because of the efficiency of early engine designs. Early developments centered around the turbojet and turboprop engines, patterned to some extent upon developments in stationary gas-turbine and steam-turbine engines. In 1930, Frank A. Whittle was granted an English patent for a turbojet engine design, but it was not until 1937 that intensive work was commenced on his design in England. The Germans initiated turbojet development in 1936 along with other jet engine and rocket motor programs. This work was carried on in an intensified manner, and the first turbojet-powered airplane flight took place in Germany in 1939. The airplane was a Heinkel HE178 powered by a Heinkel HE53B engine. Meanwhile, the Whittle engine program progressed rapidly in England. In 1941, the fourth Whittle engine, Model W1 delivering 855 pounds of thrust, propelled a Gloster E-28 airplane to 339 miles per hour at 20,000 feet. In this same year, the General Electric Company agreed to develop turbojet engines for the U.S. Army Air Forces from plans of the Whittle W2-B engine. The first American flight took place in 1942 when a Bell Aircraft P-59, powered by two General Electric IA engines of 1,300 pounds of thrust each, flew successfully. By 1944, production was started on the 4,000-pound thrust J-33 engine for the P-80 airplane. During 1944, the first axial-flow compressor turbojet engine was successfully tested by General Electric.

The three basic parts of the turbojet engine are: (1) air compressor; (2) combustion chambers; and (3) a turbine wheel(s) for driving the compressor. The compressor in the forward part of the engine draws in large quantities of air, compresses it to high pressure, and forces it through the combustion chambers. Fuel is forced through spray nozzles into the combustion chambers where it is mixed with part of the air. This mixture is then burned in a continuous combustion process and produces a very high temperature (4000 °F; ∼2205 °C or higher), which heats the entire air mass to 1600 to 2000 °F (871 to 1903 °C) or higher. The hot gases then pass through the turbine wheel(s) directly behind the combustion chambers. Part of the energy in the hot gases is used to rotate the turbine wheel, which in turn drives the compressor by means of a direct shaft. The hot gases then expand and blast out of the tailpipe nozzle at high velocity. The reaction to the momentum of the escaping gases is the thrust force that propels the airplane.

The efficiency with which the three basic parts of the turbojet engine operates, particularly the turbine wheel(s) and compressor, is very important to thrust output. Since approximately two-thirds of the energy available in the hot gases is absorbed by the turbine wheel to drive the compressor, the need for high efficiency is obvious. Early models failed because of inefficient turbine and compressor design, coupled with inferior materials of construction. Since thermodynamic laws reveal that the energy available in hot gases increases with both temperature and pressure, design development constantly strives for compressors that will provide even greater pressures and turbine wheels that will withstand higher temperatures. One of the most outstanding improvements made has been that of more effective materials for turbine-wheel blades.

Special nozzles are used to reduce the disturbing noise intensity of the jet blast during take-off. This low-frequency, high-intensity noise is caused by the turbulent mixing of jet exhaust gases with the atmosphere. Nozzles reduce the formation of large-scale eddies, lowering the intensity of the lower "rumbling" frequencies and changing the character of the sound. Also, by permitting a more rapid mixing of the jet gases with surrounding air, they increase the rate of sound-energy dissipation.

Thrust reversal to assist wheel braking during the landing roll is accomplished by stopping the aft flow of the jet and directing it partially forward in the direction of airplane movement. To prevent the hot gases from entering the compressor inlet, of the same or adjacent engines, the reverser directs the jet blast outward at a suitable angle from the nacelle. Because of this angle, and losses due to turning the path of the gases, thrust available in the reverse direction is about 40% of forward thrust for the same engine rpm.

The magnitude of thrust output of a turbojet engine is determined by the mass airflow through the engine and the velocity of the mass leaving the jet nozzle. This is expressed by previously given equation (1). That equation represents the thrust output when the engine and airplane are at rest. When the airplane and engine are in motion, air is being rammed into the engine compressor inlet, tending to retard the forward motion. This retarding force is called *ram drag* and its magnitude is determined by the mass airflow through the engine and the airplane velocity:

$$\text{Ram Drag} = MV_a \tag{5}$$

The net thrust for the engine in motion is, therefore, the *gross* thrust output minus the ram drag:

$$F = MV_J - MV_a \tag{6}$$

or

$$F = M(V_J - V_a) \tag{7}$$

Thus, the net thrust is equal to the product of mass airflow and the change in velocity through the engine. Actually, the mass flow of gases from the nozzle is increased by the amount of fuel added for combustion. However, since the airflow is about seventy times greater than fuel flow, the mass of the added fuel is neglected in basic equations.

Augmentation. This term applies to means for increasing thrust during take-off in addition to that delivered by the basic engine. *Afterburning* implies that fuel is added to the hot gases in the tailpipe after they have passed through the turbine wheel. The burning of this additional fuel greatly increases the gas temperature and correspondingly the jet velocity, resulting in as much as 50% increase in thrust. Because the hot gases pass through the tailpipe at high velocity, it is necessary to introduce the fuel through flameholders in the tailpipe similar in some respects to the flameholders used in the combustion burners. The increase in gas temperature from afterburning causes the gases to expand, which tends to increase tailpipe pressure and turbine wheel temperatures. *Water injection* can produce about 25% additional thrust. A desirable feature of this method is the small increase in engine weight over the basic engine as compared with considerable weight increase for afterburning. Water injection equipment causes little change in normal engine performance, whereas afterburning causes a slight increase in fuel flow during normal (afterburner off) operation because of the blocking effect of the flameholders in the tailpipe. Water is introduced into the

compressor or is forced through nozzles into the combustion chamber, or both. When introduced into the compressor, the water cools the air by evaporation, permitting the compressor to deliver more mass flow of air at maximum rpm. To offset the additional airflow, a signal is sent to the fuel control, increasing fuel flow slightly to heat the additional air. Thrust is increased by the increased mass airflow, plus the mass of the added water and fuel. When water is introduced into the combustion chambers (or diffuser section), the resulting increase in compressor airflow is less than by direct compressor injection. However, large amounts of water injected into the combustion chambers, plus the slight increase in compressor airflow, result in a substantial gain in thrust. In the combustion-chamber injection method, alcohol may be mixed with the water to assist in heating the added mass rather than increasing fuel flow. The injection water must be very pure to prevent mineral deposits in the machinery.

Turbojet engines can be classified by the type of compressor used. The *centrifugal compressor* was used in early engines and in some engines today. In the centrifugal compressor, air enters the rotating impeller at the center through the inlet guide vanes. Rotating at high speed, the impeller compresses the air by centrifugal action. The air passes from the rim of the impeller through a diffuser, which retards the tendency of the air to rotate with the impeller, into the combustion chambers. The *axial-flow compressor* is used on large turbojet and turbo-prop engines. An advantage is the small diameter of the compressor. Many stages can be added together without increasing the diameter of the engine. See also **Gas and Expansion Turbines**.

Turbofan Engines. These engines were developed to provide greater propulsive efficiency than obtainable with conventional turbojets. This is accomplished by increasing the total compressor airflow and reducing the net velocity of the jet. The additional airflow does not pass through the combustion chambers and turbine wheels, but is directed aft by way of a fan outside the engine cases. In one engine design, about 25% of the air from the forward compressor is ducted outside the engine case and is mixed with the hot gases before passing through the nozzle. This type of engine is called "bypass" by the British. Bypass ratios permit from 30 to 60% or more of the propulsive force to be produced by the fan. In comparison, turboprop engine designs generally permit an energy distribution of 90% for the propeller and 10% for the jet nozzle. A basic difference between the turbofan and the turboprop is that the airflow through the turbofan is controlled by design so that the air velocity relative to the fan blades is unaffected by airspeed of the airplane. This eliminates the efficiency loss at high airspeeds, which limits airspeed capability of the turboprop engine.

Turboprop Engines. Turboprop engine development began in 1926 when the English scientist Griffith proposed an axial-flow compressor and turbine engine for driving a propeller. After wind tunnel tests, development was discontinued because of the economic depression and scientific reluctance to accept the engine as having any practical significance. Following the successful development of the turbojet engine, interest was again directed toward the turboprop engine and successful flights in England and the United States were made with turboprop installations in 1945. For several years following these flights, the majority of effort was devoted to improving turbojet design in the United States and turboprop development lagged. More emphasis was placed on turboprop development in England and France during this period and the turboprop powered English Viscount 630 was placed in commercial passenger service in 1950.

Basically, the turboprop engine is a turbojet with most of the heat energy converted to shaft power by the turbine wheels, leaving very little for jet reaction. The basic parts of the engine compressor, combustion chambers, and turbine wheels are the same in both engines, except that larger or a greater number of turbine wheels are used. In most turboprop engines, the compressor rotor shaft extends forward and drives the propeller shaft through a system of reduction gears.

A significant difference exists between turboprop and turbojet engine controls. In the turbojet engine, fuel is metered by the control as required in proportion to airflow to maintain constant rpm, or is metered in the proper amount to effect changes from one rpm to another. The control must be designed to meter fuel within precise limitations to prevent overheating of the turbine wheels, compressor surge, or burner blowout. The control must also correct for varying conditions of altitude, air temperature, and airspeed for a given power lever position.

All of the control requirements of the turbojet are present in the turboprop engine with additional requirement imposed by the propeller. By means of the blade pitch-angle control, the speed and power absorption of the propeller can be varied independently of the normal engine control. In addition, the rather large inertia (resistance to rapid rpm change) of the propeller and direct-connected engine rotor further complicates the control requirements. To provide the pilot with a simple single-lever control, as used for the turbojet, the propeller control of the turboprop is integrated with the engine fuel control. With most turboprop controls, the engine is operated within a narrow range in the high-rpm region for all flight conditions. This operation minimizes the effect of propeller inertia on power changes.

Ramjet and Pulsejet Engines. The ramjet or athodyd (aerodynamic-thermodynamic-duct) was invented by Lorin in France in 1913. The pulsejet, or resonant-type jet propulsion motor, was invented in 1910, also in France. The only extensive use of the pulsejet engine was made by the Germans during World War II when it was used to propel the V-1 "buzz bomb." Intensive development of the ramjet engine principle was begun in the United States following World War II for use with long-range, high-altitude guided missiles.

Pulsejet Engines. Because of its inefficiency and principle of operation, the pulsejet engine cannot compete with the turbojet or ramjet engines and finds no practical applications. With reference to Fig. 11, the pulsejet engine consists simply of a combustion chamber with an air intake, incorporating check valves at the forward end, and a nozzle for expelling the gases at the aft end. Forward velocity is required in order to ram air into the combustion chamber to start the combustion process. With air pressure in the combustion chamber, fuel is added and the mixture is ignited by a spark plug. The resulting pressure in the chamber closes the check valves in the air inlet and forces the hot gases out of the nozzle. The velocity energy of the gases passing out of the nozzle reduces the pressure in the combustion chamber below the atmospheric level, causing the air inlet valves to open and admit a fresh charge of air. The combustion process is then repeated and, after a few cycles, is self-sustaining and requires no further spark ignition. For the engine to operate properly, it is necessary that the vibratory resonance of the air inlet valves be "tuned" with the impulses of the gases and sound waves escaping from the nozzle. This is accomplished by shortening or lengthening the tailpipe until resonance is established for the desired flight velocity. The V-1 engine used a grill of thin metal reeds, similar to reeds of a harmonica, for the air-inlet valves. The resonant frequency of explosions for the V-1 engine was approximately 200 to 300 Hz, creating the buzzing sound for which the missile was named.

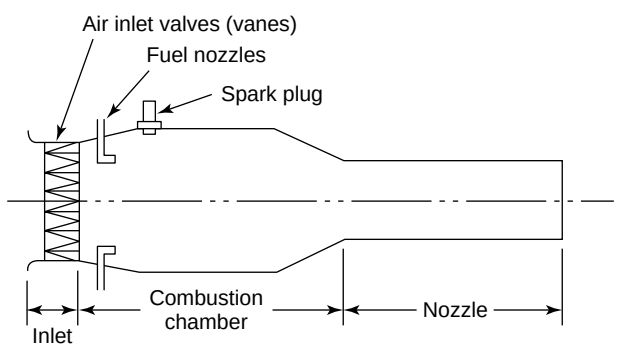

Fig. 11. Pulsejet engine.

Ramjet Engines. Mechanically, the ramjet engine represents the simplest air-breathing jet engine, since it contains no moving parts. The principal parts are shown in Fig. 12. As with the pulsejet engine, forward velocity is required for ramjet operation to induce air into the combustion chamber, or "ram" the air in, as the name implies. The forward velocity of the engine rams air into the inlet and thence into the diffuser section where the air velocity is slowed down by the divergent walls of the diffuser. In the combustion chamber, heat is added by the combustion of kerosene or other jet engine fuels which tends to expand the gases and increase their pressure. Because the entering ram air and the diffuser prevent expansion of the hot gases in a forward direction, the gases accelerate out the nozzle at a higher velocity than the velocity of the entering air. The reaction to the rearward velocity of the gases produces forward thrust.

The diffuser section is important in the functional operation of the engine. The outward taper must be carefully designed to permit proper

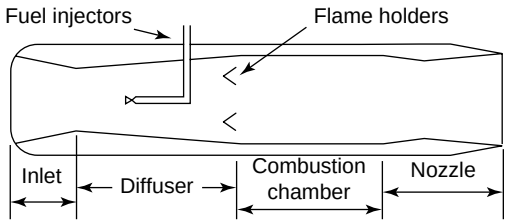

Fig. 12. Ramjet engine.

slowing of the ram air with a minimum of losses. The shape of the air inlet is equally important, as is the design of the nozzle. In ramjet engines, combustion is continuous after having been started by spark ignition or other methods. Because of the rather high velocity in the combustion chamber (300 to 500 feet (91 to 152 meters) per second), flameholders are required, as in the combustion chambers of turbojet engines.

For long-range missile applications, provided the missile remains at an altitude where there is sufficient oxygen, the ramjet engine has the advantages of light weight and no requirement for oxidizing chemicals (also keeping the weight down). These advantages also spell out low initial cost.

Modern Jet Engines. Sir Frank Whittle (United Kingdom) and Hans J.P. von Ohain (Germany) independently invented jet engines with improved features. Development of jet-powered military aircraft commenced during the late phases of World War II. During that period the Germans developed the fastest jet-powered military aircraft — a plane that achieved a speed of about 525 miles (845 kilometers) per hour. However, the lifetime of the aircraft was about 25 hours. This jet engine life was cost prohibitive. By comparison, modern jet engines have a lifetime ranging from 10,000 to 20,000 hours. The early jet engines developed pounds force of thrust from 1,000 to 2,000 pounds (4.5 to 9 kN). Modern jet engines develop up to 80,000 pounds of thrust. Pressures created in the combustion chambers of modern jet engines range up to 35 times that of the outside air. Combustion chamber temperatures now range up to 2900 °F (1503 °C) as compared with 1500 °F (815 °C) of the early jet engines. Fuel efficiency has increased by approximately a factor of 3 as compared with earlier piston engines. These performance increases have stemmed from the engine's internal design and the development and selection of superior materials.

In 1991, Sir Frank Whittle (now adjunct research professor at the U.S. Naval Academy, Annapolis, Maryland) and J.P. von Ohain (Senior Research Engineer, University of Dayton Research Institute, Dayton, Ohio) were jointly awarded the esteemed Charles Stark Draper Award for outstanding achievements in engineering. Of course, the engineering staffs of General Electric and Pratt & Whitney, among other specializing firms, also contributed to the modern jet engine for aircraft.

The engine for the new McDonnell Douglas MD-11 series of airplanes, previously mentioned, was a high-bypass ratio 94-inch (2,387-millimeter) turbofan engine, ranging from 50,000 to 62,000 pounds (224 to 278 kN) pounds force of thrust. See Fig. 13. The PW 4000 (Pratt & Whitney) engine also was suitable for use on current wide-body aircraft. See Fig. 14. The engine for the Boeing 777 previously mentioned was a high-bypass ratio 112-inch (2,845-millimeter) turbofan engine, ranging from 77,000 to 98,000 pounds (345 to 439 kN) pounds force of thrust. These engines, shown in Figs. 15, 16, 17, and 18, were designed to provide 7% better fuel economy for the same size engine. Also the innovative designs had 50% fewer parts, which translated into fewer spare parts inventorying problems and less maintenance time.

Historical Aircraft

Early History. The following paragraphs are included here for those readers who may be interested in the early days of aircraft. Difficult to comprehend for all but the older readers, the early days of flying were indeed thrilling times and the phrase "air minded" was very popular in that era preceding the late 1930s. There was much competition in terms of aircraft performance and pilots. Unquestionably, the major meets and well-funded competitions, such as the Gordon Bennett Cup, the Schneider Cup, the Pulitzer Trophy, the Thompson Trophy, and the Bendix Trophy greatly catalyzed the development of superior airplanes. The progress in airplane design also was grossly assisted during the two major World Wars. It is sometimes difficult to realize, in perspective, that modern massive movements of people and cargo by air all have occurred within the life

span of many people still living. Progress made during the early period of 1906 to 1914 is shown in Fig. 19. The speed records of the major competitions held during the period 1909 to 1939 are plotted in Fig. 20. The Reims (France) Meet of 1909 was the first extensive meet in aircraft

history. The Gordon Bennett meets, commenced in 1909, were the first airplane speed races. The Schneider Cup meets were designed to promote the advancement of seaplanes and flying-boats and were confined to that category of aircraft. A primary incentive of the Pulitzer Trophy races was that of promoting the design of more effective fighter aircraft for the military. These meets were abandoned when U.S. General Mitchell was court-martialed. The Thompson Trophy races were sponsored by Cleveland industrialist, Charles E. Thompson, and were geared to speed. The Bendix Trophy races were of a different nature, namely, cross-country flights from Burbank, California to Cleveland, Ohio, and thus the speeds represented an average over long straight distances. These races highlighted the role of

women as competent pilots, the 1938 race having been won by Jacqueline Cochran.

There was essentially no aircraft industry at the time of World War I in the United States, with just a little over 50 planes produced in 1916. The war, however, hastened design and production activities even though few American planes were used during the war. American pilots mainly flew French aircraft. The French introduced nearly 20 new planes during the period between 1914 and 1917. The fastest of these was the Spad S XIII, with a speed of 130 miles (209 kilometers) per hour and a ceiling of 22,300 feet (6797 meters). It had a 200-horsepower Hispano-Suiza engine and a wingspan of just a little over 26 feet (7.9 meters). The British also introduced nearly 20 planes during the same period. The S.E.5a was the fastest plane of that period, reaching a top speed of 138 miles (222 kilometers) per hour. It was powered by a 200-horsepower Wolseley Viper engine, had a wingspan of nearly 27 feet (8.2 meters), a range of about 340 miles (547 kilometers), and a ceiling of 19,500 feet (5944 meters).

Although Italy only introduced seven aircraft during the 1915–1917 period, it was the first country to employ aircraft in warfare. The fastest of the Italian planes was the Ansaldo S.V.A-5, with a speed of 143 miles (230 kilometers) per hour, powered by a 220-horsepower S.P.A. 6A engine, a wingspan of 32 feet (9.8 meters), and a ceiling of 22,000 feet (6706 meters). The fastest plane produced by the Germans was the Hansa-Brandenburg D1, with a speed of 116 miles (187 kilometers) per hour, a wingspan of a little over 26 feet (7.9 meters), powered by a 160-horsepower Austro-Daimler engine. It had a ceiling of 16,400 feet (4999 meters). Probably the most famous of the German World War I planes were those in the Albatros series, most of which were powered by Mercedes engines. The first airplane to have a machine gun synchronized with the propeller was the Fokker E-III, introduced in 1915. Other famous names in production in Germany during the war period included the Etrich A-11 Taube, introduced in 1910 and extensively used for pilot training; the Fokker E-III and D-VII; the LVG C-1, the Rum per C-1; the Lloyd C-II (Austrian); the Pfalz D-III; the Hannover CL-IIIa; the Gotah G-VIII; the Friedrichshafen G-III (a heavy bomber). The Zeppelin R-VI (not to be confused with a dirigible) was also introduced during that period.

Airplanes of World War II. Airplane production during the period just prior and carrying through the war years numbered in the tens of thousands, notably in the United States, Great Britain, Germany, Russia, and Japan. It is interesting to note that concentration on production of conventional propeller airplanes essentially delayed final development and refinement of jet aircraft during that period. The only true jet aircraft to see action during World War II were the British-built Gloster Meteor III

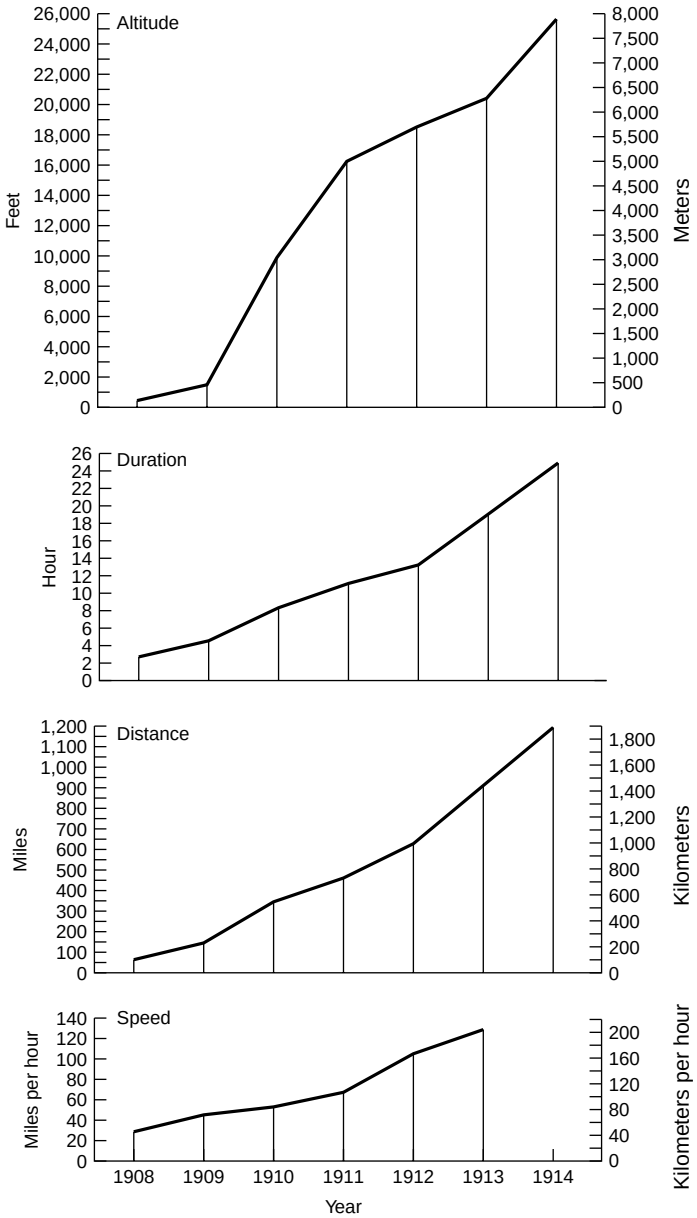

Fig. 19. Records set by early airplanes during period (1908–1914).

and the German-built Me-262 jet fighters. The first mission for the Meteors, of which 280 were produced, was set for mid-April 1945 for the purpose of intercepting the German jet fighters. The encounter did not occur, however, and the war was ended without the Meteors seeing action. The meteors were equipped with two jet engines, each capable of 2000 pounds (907 kilograms) of thrust. They had a speed of 493 miles (793 kilometers) per hour, a range of 1340 miles (2156 kilometers) and a ceiling of 44,000 feet (13,411 meters)—with a crew of one. The German Messerschmitt Me-262A Sturmvogel was commissioned in mid-1942, but did not see action until mid-1944. Nearly 1,500 of these aircraft were produced, but only about 400 saw action during the war. The Sturmvogels were equipped with two jet engines, each capable of 1984 pounds (900 kilograms) of thrust. They had a speed of 541 miles (871 kilometers) per hour, a range of 650 miles (1046 kilometers), and a ceiling of a little over 37,500 feet (11,430 meters)—with a crew of one. Also of interest was the Messerschmitt Me-163B Komet. It was the first and, in fact, only rocket-propulsion fighter of the war. It was first commissioned at the end of July 1944. The craft had extremely limited performance parameters—flying time, about 10 minutes; altitude, about 6.2 miles (10 kilometers) (in 2.5 minutes). About 350 were produced and it is reported that more of these aircraft exploded upon landing than were knocked out by Allied fighters. The single power plant of the Komet was capable of producing about 3,750 pounds (1,701 kilograms) of thrust, with a maximum flying speed of just under 600 miles (965 kilometers) per hour. It carried a crew of one. The Japanese Yokosuka MXY7 Ohka 22, also known as the kamikaze or suicide aircraft, was equipped with a single jet engine in the tail. The little craft with a wingspan of under 14 feet (4.3 meters) and length of about 23 feet (7.0 meters), carried a 1,300-pound (590 kilograms) charge of dynamite. In operation, the Ohka was carried near its target by a G4M2e, at which time the Ohka was piloted for a short distance to the target, with no escape for the pilot just prior to impact.

The war faced a challenge in refurbishing the fleets of not only the various airlines in the United States which had been utilized to the full during the war, but also of demands for aircraft by much of the rest of the world. Jet engine and jet technology, in general, still was not quite ready for application in large commercial planes and required further testing and refining in military aircraft, for which funding was available. Thus, during the late 1940s and early 1950s, a number of interesting and well-designed and performing propeller aircraft were introduced.

The first jet passenger service was offered by BOAC in early May 1952. The plane used was the DeHavilland DH 106 Comet. A couple of accidents in 1954 precipitated early retirement for these airplanes. However, in 1958, a new version, the Comet 4, was introduced. About 75 of these airplanes were built. The early Comet 1 was powered by 4 jet engines, each with a thrust of 4,450 pounds (2019 kilograms). The wing spread was 115 feet (35 meters), the cruising speed was 490 miles (788 kilometers) per hour, with a ceiling of 35,000 feet (10,668 meters). The airplane could accommodate up to 44 passengers with a crew of 4.

The Boeing 707-121 made its first flight in mid-July 1954. However, it was not used for nonstop flights across the Atlantic until late 1958. This airplane generally is considered as one of the most successful passenger aircraft of all times. The early airplane was powered by 4 jet engines, each producing a thrust of 13,000 pounds (58 kN). The wing spread was 130 feet (39 meters), cruising speed 585 miles (941 kilometers) per hour, a range of 3,750 miles (6034 kilometers), and ceiling of 36,000 feet (10,973 meters). At maximum loading, it could accommodate 189 passengers with a crew of 4.

The Sud-Aviation SE-210 Caravelle made its first flight in late May 1955. It commenced commercial passenger service in Europe in 1959. Nearly 300 aircraft of the SE-210 were produced and, of course, there have been subsequent model changes. The SE-210 was powered by 2 jet engines, each with 10,500 pounds (47 kN) of thrust, wing spread was nearly 113 feet (34 meters), cruising speed 456 miles (734 kilometers) per hour, a range of 1150 miles (1850 kilometers), and ceiling of 30,000 feet (9144 meters). Maximum capacity was 80 passengers with a crew of 3.

In recent years, great emphasis has been placed upon the use of stronger, lighter-weight materials — both in military and passenger aircraft. See Fig. 21.

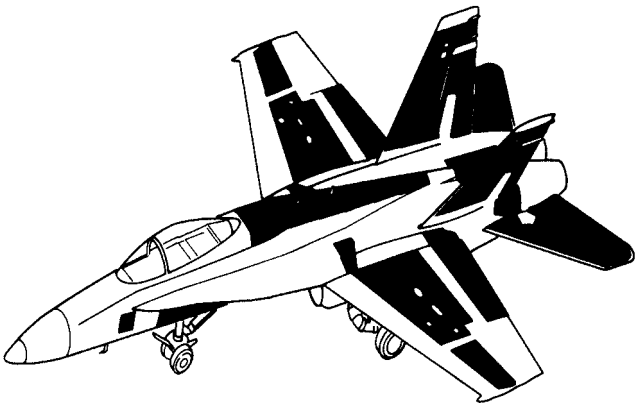

Fig. 21. Airframe of the F/A-18 strike fighter aircraft is a balance of conventional materials and graphite epoxy providing an optimum lightweight structure. The wing skins, trailing edge flaps, stabilizers, vertical tails and rudder, speed brake, and many access doors are made of graphite composite materials comprising about 9.9% of the aircraft structural weight and resulting in appreciable weight savings, plus increased aircraft performance. Other materials used (as a percent of structural weight) include aluminum, 49.6%; steel,16.7%; titanium, 12.9%; other materials, 10.9%. (*McDonnell Douglas Corporation*.)

The problems of the supersonic passenger aircraft (*Concorde*) in terms of economic viability are well known. Periodically, interest is indicated in other supersonic passenger carriers that, because of the impressive advancements made in aircraft technology over the last several years, possibly could be economically and otherwise attractive to the commercial airlines.

AIR PLOT. A plot showing the movements of an airplane relative to the air is known, in navigation, as an air plot. It is similar in every respect to the old-fashioned method for obtaining the dead reckoning (DR) position of a sea-borne ship, disregarding the effects of ocean currents.

The air plot is made up of a series of distance vectors, added in the usual manner, the direction of each vector being a heading of the plane and the length being proportional to the distance moved through the air along the heading (distance = air speed × time on heading). The summation of the vectors gives a no wind (NW) position of the plane at any time. To obtain the DR position of the plane it is only necessary to add the total wind vector, whose direction is that of the motion of the air and whose length is the total movement (wind speed × total time since departure) of the air, to the NW position. Such a method avoids the necessity of constructing the velocity-vector diagram to obtain course and speed along course for each heading, as is necessary in the standard method for obtaining a DR position in air navigation.

In cases where the plane is frequently changing headings, the air-plot method saves from 30–60% of the time involved in obtaining the DR position by standard methods. Furthermore, in the frequent cases where the predicted wind for high altitude is very inaccurate, the air plot provides a method for determining the wind.

The solution of the following problem indicates that advantages and value of the air plot. On a day when the predicted winds are uncertain, a plane is to search an area centered about a point in latitude L = 42 °22′ N and longitude Lo = 35 °25′ W. The plan e, flying with true air speed TAS = 130 knots at altitude 10,000 feet (3,000 meters) is over the point at 0500 and heads 150°. The altitude and air speed are maintained, but the plane alters headings at the given times as follows: 0510 heading 240°, 0520 heading 330°, 0540 heading 060°, 0600 heading 150°, 0640 heading 240°. The air plot, properly labeled, is shown in the figure from which the NW position at 0700 is found to be L = 41 °15′ N and Lo = 35 °07′ W.

The predicted wind at the altitude of flight is from 000° and speed 35 knots. From the 0700 NW position a vector in direction 180° and of length 70 miles (112 kilometers) is drawn. This is shown as a dotted line in Fig. 1. and represents the total movement of the plane due to the predicted wind in the two hours from 0500. This gives a dead-reckoning position in latitude 40 °05′ N and longitude 35 °07′ W.

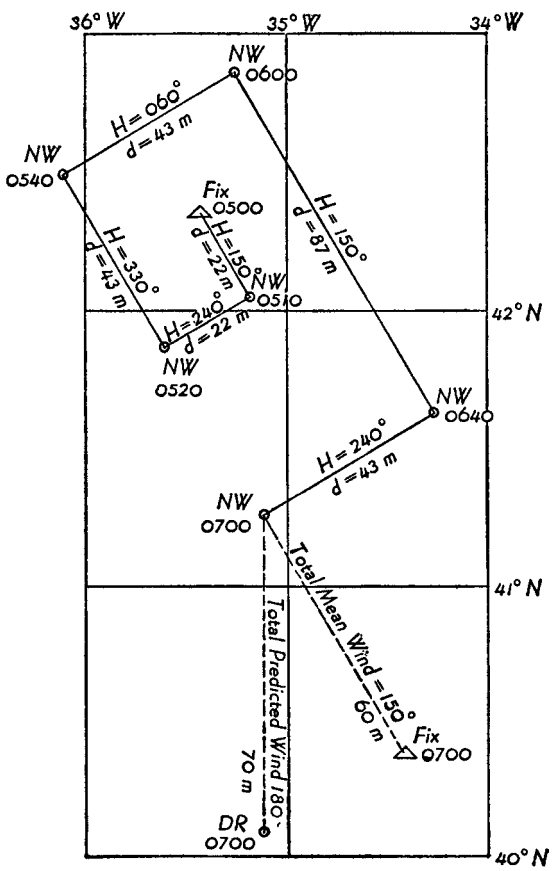

Fig. 1. Scale figure for air plot.

A fix is obtained at 0700 in latitude 40°23′ N and longitude 34°27′ W. If a vector is drawn from the NW position to the fix, it will represent the actual movement of the air in the interval from 0500 to 0700. From the diagram this is found to be in the direction 150° and 60 miles (96 kilometers) long. Since this represents 2 hours total motion of the air, we have a mean wind from 330°, speed 30 knots.

To obtain the DR position, using the standard methods of dead reckoning, would have required the plotting of at least four velocity-vector diagrams to obtain the course and ground speed on each heading. Each of these would have taken at least twice as much time as is required to plot an air vector and, after the courses and ground distances had been obtained, the geographic-motion vector diagram would have had to be plotted. Then to obtain the mean wind, the assumed air motion would have had to be subtracted from the DR position to obtain the NW position, which has to be used with the fix to obtain the actual total wind motion. See also **Course**; **Dead Reckoning**; **Heading**; and **Navigation**.

AIR POCKET. See **Meteorology**.

AIR POLLUTION. Air pollution is a broad term applied to any chemical, physical (particulate matter), or biological agent that modifies the natural characteristics of the atmosphere. These substances are generally contaminants that substantially alter or degrade the quality of the atmosphere. The term is often used to identify undesirable substances produced by human activity, that is, anthropogenic air pollution. Air pollution usually designates the collection of substances that adversely affects human health, animals, and plants; deteriorates structures; interferes with commerce; or interferes with the enjoyment of life. See also **Clean Air Act**; and **Pollution (Air)**.

Sources

Air pollutants are classified as either directly released or formed by subsequent chemical reactions. A direct release air pollutant is one that is emitted directly from a given source, such as the carbon monoxide or sulfur dioxide, all of which are byproducts of combustion; whereas, a subsequent air pollutant is formed in the atmosphere through chemical reactions involving direct release pollutants. The formation of ozone in photochemical smog is the most important example of a subsequent air pollutant. See also **Ozone**.

Anthropogenic Sources. These sources are the result of human activity and related to burning different kinds of fuel:

- Combustion-fired power plants.
- Controlled burn practices used in agriculture and forestry management.
- Motor vehicles generating air pollution emissions.
- Marine vessels, such as container ships or cruise ships, and related port air emissions.
- Wood, coal, fuel oil or natural gas burning fireplaces, stoves, furnaces and incinerators.

Other Anthropogenic Sources.

- Oil refining, power plant operation and industrial activity in general.
- Chemicals, dust and crop waste burning in farming.
- Fumes from paint, varnish, aerosol sprays and other solvents.
- Waste deposition in landfills, which generate methane.
- Military uses, as nuclear weapons, toxic gases, germ warfare and rocketry.

Natural Sources.

- Dust from natural sources, usually large areas of land with little or no vegetation.
- Methane, emitted by the digestion of food by animals, for example cattle.
- Pine trees, which emit volatile organic compounds (VOCs).
- Radon gas from radioactive decay within the Earth's crust.
- Smoke and carbon monoxide from wildfires.
- Volcanic activity, which produce sulfur, chlorine, and ash particulates.

Contaminants. Important pollutant gases include:

- Carbon monoxide (CO) [CAS: 630-08-0], which is primarily emitted from vehicle exhausts due to incomplete combustion; the highest concentrations are generally found near roadways. Inhalation of high levels of carbon monoxide can cause headaches, fatigue, respiratory problems and death. See also **Carbon Monoxide**.
- Chlorofluorocarbons, which destroy the stratospheric ozone layer.
- Hydrocarbons, examples: methane (CH_4) [CAS: 74-82-8], ethane (C_2H_6) [CAS: 74-84-0], propane (C_3H_8) [CAS: 74-98-6], butane (C_4H_{10}) [CAS: 106-97-8], hexane (C_6H_{14}) [CAS: 110-54-3].
- Nitrogen oxides (NO_x). Emissions are primarily in the form of nitric oxide (NO) [CAS: 10102-43-9], which is oxidised by atmospheric ozone or peroxy radicals to form Nitrogen dioxide (NO_2) [CAS: 10102-44-0]. NO_2 is the primary concern for effects on health, and is the species for which WHO's health-based standards are expressed. The various oxides of nitrogen can also react with hydrocarbons in the atmosphere to contribute to photochemical smog. NO_x can also affect ecologically sensitive sites through deposition, causing acidification and eutrophication. See also **Nitrogen**.
- Sulfur oxide (SO_x), which causes acid rain is derived from the burning of fuel containing sulfur, mostly at power plants, and during metal smelting and other industrial processes. See also **Acid Rain**.
- Tropospheric ozone, which is ozone in the lower part of the atmosphere. Ozone (O_3) [CAS: 10028-15-6] is a secondary pollutant, formed through photochemical reactions involving NO_x and hydrocarbons; it is an irritant gas. In the stratosphere it helps to reduce the amount of ultraviolet radiation from the sun that reaches Earth.
- Volatile organic compounds: gasoline, solvents, cleaning solutions.

Particulates are small particles, classified by diameter. Atmospheric particles are usually measured as PM10 or PM2.5. The smaller the particle, the more hazardous it is to health. The PM10 fraction are particles with an aerodynamic diameter of less than 10 micrometres; these can be breathed deep into the respiratory tract and reach the lungs. PM2.5 particles are even more dangerous because they can pass through the upper airway filtering into the alveoli, where they can cross the lung/blood stream barrier and enter the bloodstream. Even smaller nanoparticles can stay airborne longer and are thence more important, besides which these minute particles tend to be more toxic.

Important pollutant particulates (mostly from combustion sources) include:

- Hydrocarbon solids (commonly from inefficiently burned fuels).
- Suspended oil particles (from aerosol spray sources).
- Elemental carbon (soot).
- Elemental sulfur.
- Mineral salts, though these can occur naturally.
- Lead and other toxic heavy metals.
- combinations of ammonia (NH_3) with either sulfuric acid (H_2SO_4) or nitric acid (HNO_3) and water (H_2O)—secondary emissions.
- Asbestos fibers.

AIR POLLUTION METEOROLOGY. See **Meteorology**.

AIR PREHEATER. There are many devices whose purpose is to heat air for some specific usage. However, in speaking of air preheaters, what is ordinarily meant is the heater employed for raising the temperature of air used for combustion of a fuel. This may occur in some industrial process such as preliminary heating of the air supplied to blast furnaces, but the most frequent use of air preheaters today is in connection with steam boilers. This type of air preheater is a heating surface installed between the boiler flue gas outlet and the stack. In arrangement the heating surface is composed either of tubes with flue gas inside and the air to be heated outside, or of rectangular plates spaced about one-half inch (13 millimeters) apart, leaving alternate gas and air passages. Its use is chiefly justified on economic grounds.

Two principles are employed for heat transfer in air preheaters. The recuperative principle implies transfer of heat through a separating partition, such as the walls of a tube, by continuously recuperating the cool side with conduction of heat from the hot side. Regenerative heaters are those which alternately heat and cool the same mass, regenerating it thermally by passing hot spent gas over its surface.

AIR QUALITY CRITERIA. Quantitative and qualitative indications of the relationships between exposure to pollutants and effects on human health, animals, plants, and materials.

These are descriptive effects of pollution as a function of concentration averaged over various time durations. A time-averaged concentration is used because exposure to a high concentration of pollutants during a

short time might have an impact equivalent to an exposure to a lower concentration over a longer time. See also **Air Quality Standards**.

AIR QUALITY MODELS. Air quality models use mathematical and numerical techniques to simulate the physical and chemical processes that affect air pollutants as they disperse and react in the atmosphere. Based on inputs of meteorological data and source information like emission rates and stack height, these models are designed to characterize primary pollutants that are emitted directly into the atmosphere and, in some cases, secondary pollutants that are formed as a result of complex chemical reactions within the atmosphere. These models are important to our air quality management system because they are widely used by agencies tasked with controlling air pollution to both identify source contributions to air quality problems and assist in the design of effective strategies to reduce harmful air pollutants. For example, air quality models can be used during the permitting process to verify that a new source will not exceed ambient air quality standards or, if necessary, determine appropriate additional control requirements. In addition, air quality models can also be used to predict future pollutant concentrations from multiple sources after the implementation of a new regulatory program, in order to estimate the effectiveness of the program in reducing harmful exposures to humans and the environment. Air quality models can be broadly categorized into the following types.

Box Models

These are the simplest of the numerical models for air quality modeling. The region to be modeled is treated as a single cell, or box, bounded by the ground at the bottom, and some upper limit to the mixing on the top, and the east-west and north-south boundaries on the sides. Here, the pollutant concentrations in a volume of air, a "box", are spatially homogeneous and instantaneously mixed. Under these conditions, the pollutant concentrations can be described by a balance among the rates they are transported in and out of the volume, their rates of emissions, and the rates at which pollutants react chemically or decay. Since these models lack spatial resolution, they cannot be used in situations where the meteorological or emissions patterns vary significantly across the modeling region.

Grid Models

Grid models employ a fixed Cartesian reference system and divide the modeling region into a two- or three-dimensional array of uniform grid cells. Horizontal dimensions of each cell usually measure on the order of kilometers (miles), while vertical dimensions can vary from a few meters (feet) to a few hundred meters (feet). One example of the grid models is The Variable Grid Uban Airshed Model® (UAM-V®) System briefly described latter in this entry.

Grid models as currently designed are generally not capable of resolving pollutant concentrations at the microscale — that is, at scales smaller than the size of a grid cell. Thus, important local effects, such as high pollutant concentrations in the immediate vicinity of point sources, tend to become obscured by the averaging of pollutant concentrations over the grid cell volume.

There are practical and theoretical limitations to the minimum grid cell size. Increasing the number of cells increases computing and data acquisition effort and costs. In addition, choice of a grid cell implies that the input data, such as the wind flows, turbulence, and emissions, are resolved to that scale. In practice, most applications employ grid cell sizes of a few kilometers. Further, the assumptions involved in the formulation of the atmospheric diffusion equation make it applicable for gird models with horizontal resolution coarser than 2 km (1.2 miles).

These models are used to assess the effectiveness of emissions reductions at a urban/regional scale. In essence, considering the domain-wide effects of emissions reductions. As these models assume uniform conditions within each grid cell, all the local scale processes are lumped into one average quantity.

Trajectory Models

The trajectory models use a moving coordinate approach to describe pollutant transport. Here, the atmospheric diffusion equation is solved in an air parcel of interest, which is assumed to travel solely with the horizontal wind. These models give results only on the path of traversed by the air parcel described, and do not permit construction of the spatial and temporal variation of concentrations over the entire region. However, their utility is in the calculation of extreme concentrations that are typically found in the plumes from point sources.

Since the numerical grids used in grid models are considerably large in size (on the length scales of a few kilometers), an understanding of the "sub-grid" effects is important in order to assess local scale effects. In order to describe the sub-grid phenomena, with specific emphasis on establishing causal relationships between emissions from point sources (such as industrial stacks) and the pollutant concentrations in the neighborhood of the point sources, plume models are employed. Plume models are trajectory models that describe short term behavior of the plume of emissions from a point source. The typical time scales range from 1 hour to 24 hours, with length scales ranging from a few hundred meters (feet) to a few kilometers (miles). Such detail cannot be achieved by increasing the resolution of grid-based models, since the model formulation of the grid-based models is not valid for finer resolutions (i.e., less than 2 km (1.2 miles) length scales).

The most commonly used air quality models include the following:

Dispersion Modeling

These models are typically used in the permitting process to estimate the concentration of pollutants at specified ground-level receptors surrounding an emissions source. Based on emissions and meteorological inputs, a dispersion model can be used to predict concentrations at selected downwind receptor locations. These air quality models are used to determine compliance with National Ambient Air Quality Standards (NAAQS), http://www.epa.gov/air/criteria.html, and other regulatory requirements such as New Source Review (NSR), http://www.epa.gov/nsr/ and Prevention of Significant Deterioration (PSD) regulations, http://apps.leg.wa.gov/wac/default.aspx?cite=173-400-720. These models are addressed in Appendix A of EPA's *Guideline on Air Quality Models* (also published as Appendix W of 40 CFR Part 51), http://www.epa.gov/scram001/guidance/guide/appw_05.pdf, which was originally published in April 1978 to provide consistency and equity in the use of modeling within the U.S. air quality management system. These guidelines are perodically revised to ensure that new model developments or expanded regulatory requirements are incorporated. Links for dispersion models and other related tools and information are as follows:

Preferred/Recommended Models

These refined dispersion models are listed in Appendix W and are required to be used for State Implementation Plan (SIP), http://www.epa.gov/region4/air/sips/, revisions for existing sources and for New Source Review (NSR) http://www.epa.gov/nsr/ and Prevention of Significant Deterioration (PSD) programs http://www.epa.gov/nsr/psd.html. The models in this section include the following:

AERMOD Modeling System. A steady-state plume model that incorporates air dispersion based on planetary boundary layer turbulence structure and scaling concepts, including treatment of both surface and elevated sources, and both simple and complex terrain. See also http://www.epa.gov/scram001/7thconf/aermod/aermodugb.pdf.

CALPUFF Modeling System. A non-steady-state puff dispersion model that simulates the effects of time- and space-varying meteorological conditions on pollution transport, transformation, and removal. CALPUFF can be applied for long-range transport and for complex terrain. See also http://www.epa.gov/scram001/dispersion_prefrec.htm#calpuff.

Other Models. Other dispersion models including *Buoyant Line and Point Source Dispersion Model* (*BLP*), http://www.epa.gov/scram001/userg/regmod/blpug.pdf, *CALINE3*, http://www.epa.gov/scram001/userg/regmod/caline3.pdf, *CAL3QHC/CAL3QHCR*, http://www.epa.gov/scram001/dispersion_prefrec.htm, *Complex Terrain Dispersion Model Plus Algorithms for Unstable Situations* (*CTDMPLUS*), http://www.epa.gov/scram001/userg/regmod/ctdmplusvol1.pdf, and *Offshore and Coastal Dispersion Model* (*OCD*), http://www.epa.gov/scram001/userg/regmod/ocdugsup.pdf.

See also http://www.epa.gov/scram001/dispersion_prefrec.htm.

Alternative Models

The dispersion models listed here are alternatives to the preferred/recommended models listed in the *Guideline on Air Quality Models*, http://www.epa.gov/scram001/guidance_permit.htm#appw, which can be used in regulatory applications with case-by-case justification to the Reviewing Authority. The models in this section include:

Air Force Dispersion Assessment Model (ADAM). ADAM is a modified box and Gaussian dispersion model which incorporates thermodynamics, chemistry, heat transfer, aerosol loading, and dense gas effects. Release scenarios include continuous and instantaneous, area and point, pressurized and unpressurized, and liquid/vapor/two-phased options.

Atmospheric Dispersion Modeling System (ADMS-3). ADMS-3 is an advanced dispersion model for calculating concentrations of pollutants emitted both continuously from point, line, volume and area sources, or discretely from point sources. The model includes algorithms which take account of the following: effects of main site buiding; complex terrrain; wet deposition, gravitational settling and dry deposition; short term fluctuations in concentration; chemical reactions; radioactive decay and gamma-dose; plume rise as a function of distance; jets and directional releases; averaging time ranging from very short to annual; condensed plume visibility; meteorological preprocessor. See also http://www.cerc.co.uk/epa/index.htm.

USAF Toxic Chemical Dispersion Model (AFTOX). AFTOX is a Gaussian dispersion model that will handle continuous or instantaneous liquid or gas elevated or surface releases from point or area sources. Output consists of concentration contour plots, concentration at a specified location, and maximum concentration at a given elevation and time.

The Assessment System for Population Exposure Nationwide (ASPEN). ASPEN consists of a dispersion and a mapping module. The dispersion module is a Gaussian formulation based on ISCST3 for estimating ambient annual average concentrations at a set of fixed receptors within the vicinity of the emission source. The mapping module produces a concentration at each census tract. Input data needed are emissions data, meteorological data and census tract data. The *Emissions Modeling System for Hazardous Pollutants* (*EMS-HAP*) is needed to process the emission inputs into the ASPEN model or the ISC3 model. The ASPEN model was used in estimating annual ambient concentrations for air toxics pollutant in the National Air Toxics Assessment (NATA) Study, http://www.epa.gov/ttn/atw/nata/.

A Dispersion Model for Elevated Dense Gas Jet Chemical Release (DEGADIS). DEGADIS simulates the atmospheric dispersion at ground-level of area source dense gas (or aerosol) clouds released with zero momentum into the atmospheric boundary layer over flat, level terrain. The model describes the dispersion processes which accompany the ensuing gravity-driven flow and entrainment of the gas into the boundary layer. See also http://www.epa.gov/scram001/userg/other/degugv2.pdf.

HGSYSTEM. HGSYSTEM is a collection of computer programs designed to predict the source-term and subsequent dispersion of accidental chemical releases with an emphasis on denser-than-air (dense gas) behavior. See also http://www.ntis.gov/search/product.asp?ABBR=PB96501960&starDB=GRAHIST,

HOTMAC/RAPTAD. This model is a 3-dimensional Eulerian model for weather forecasting; RAPTAD is a 3-dimensional Lagrangian random puff model for pollutant transport and diffusion. These models are used for prediction of transport and diffusion processes for complex terrain, coastal regions, urban areas, and around buildings where conventional models fail. See also http://www.ysasoft.com/index05.htm,

The Hybrid ROADway Model (HYROAD). HYROAD integrates three historically individual modules that simulate the effects of traffic, emissions and dispersion. The traffic module is a microscale transportation model which simulates individual vehicle movement. The emission module uses speed distributions from the traffic module to determine composite emission factors; spatial and temporal distribution of emissions is based on the vehicle operation simulations. The model tracks vehicle speed and acceleration distributions by signal phase per 10-meter (33 foot) roadway segment for use in both emissions distribution and for induced flows and turbulence. The dispersion module uses a Lagrangian puff formulation, along with a gridded non-uniform wind and stability field derived from traffic module outputs, to describe near-roadway dispersion characteristics. HYROAD is designed to determine hourly concentrations of carbon monoxide (CO) or other gas-phase pollutants, particulate matter (PM) and air toxics — in consultation with appropriate Reviewing Authority — from vehicle emissions at receptor locations that occur within 500 meters (1,640 feet) of the roadway intersections. See also http://www.epa.gov/scram001/dispersion_alt.htm.

Industrial Source Complex (ISC3). ISC3 is a steady-state Gaussian plume model which can be used to assess pollutant concentrations from a wide variety of sources associated with an industrial complex. This model can account for the following: settling and dry deposition of particles; downwash; point, area, line, and volume sources; plume rise as a function of downwind distance; separation of point sources; and limited terrain adjustment. ISC3 operates in both long-term and short-term modes. The screening version of ISC3 is SCREEN3. ISC3 also uses the *Emissions Modeling System for Hazardous Pollutants* (*EMS-HAP*) to process an emission inventory for input into the model. The *Building Profile Input Program* (*BPIP*) and the *Building Profile Input Program for PRIME* (*BPIPPRM*) can also be used with ISC3 to correctly calculate building heights (bh) and projected building widths (pbw) for simple, multi-tiered, and groups of structures. See **screening models** below.

ISC-PRIME (Plume Rise Model Enhancements). This is a model with building downwash incorporated into the Industrial Source Complex Short Term Model (ISCST3). See also http://www.epa.gov/scram001/7thconf/iscprime/useguide.pdf.

Open Burn/Open Detonation Dispersion Model (OBODM). OBODM is intended for use in evaluating the potential air quality impacts of the open burning and detonation (OB/OD) of obsolete munitions and solid propellants. OBODM uses cloud/plume rise dispersion, and deposition algorithms taken from existing models for instantaneous and quasi-continuous sources to predict the downwind transport and dispersion of pollutants released by OB/OD operations. See also http://www.epa.gov/scram001/userg/nonepa/obodmvol1.pdf.

OZIPR. OZIPR is a one-dimensional photochemical box model that is an alternative version of the OZIP model that deals with air toxic pollutants. See also http://www.epa.gov/scram001/userg/other/ozipr.pdf,

Panache. Panache is an Eulerian (and Lagrangian for particulate matter), 3-dimensional finite volume fluid mechanics model designed to simulate continuous and short-term pollutant dispersion in the atmosphere, in simple or complex terrain. See also Transoft US. Inc., http://www.fluidyn.com/Home_English/Home_English.htm.

PLUVUEII. PLUVUEII is a model used for estimating visual range reduction and atmospheric discoloration caused by plumes resulting from the emissions of particles, nitrogen oxides, and sulfur oxides from a single source. The model predicts the transport, dispersion, chemical reactions, optical effects and surface deposition of point or area source emissions.

Second-order Closure Integrated PUFF Model (SCIPUFF). SCIPUFF is a Lagrangian puff dispersion model that uses a collection of Gaussian puffs to predict three-dimensional, time-dependent pollutant concentrations. In addition to the average concentration value, SCIPUFF provides a prediction of the statistical variance in the concentration field resulting from the random fluctuations in the wind field. See also http://www.epa.gov/scram001/7thconf/information/scipuff.pdf.

Shoreline Dispersion Model (SDM). SDM is a multiple-point Gaussian dispersion model that can be used to determine ground level concentrations from tall stationary point source emissions near a shoreline.

SLAB is a model which treats denser-than-air releases by solving the one-dimensional equations of momentum, conservation of mass, species, and energy, and the equation of state. SLAB handles release scenarios including ground level and elevated jets, liquid pool evaporation, and instantaneous volume sources.

Screening Models

Models that are often applied before applying a refined air quality model to determine if refined modeling is needed. The models in this section include:

AERSCREEN. This is the screening model for AERMOD. The model will produce estimates of regulatory design concentrations without the need for meteorological data and is designed to produce concentration that are equal to or greater than the estimates produced by AERMOD (see **Preferred/Recommended Models**) with a fully developed set of meteorological and terrain data.

COMPLEX1. This is a multiple point source screening technique with terrain adjustment that incorporates the plume impaction algorithm of the *VALLEY* model.

CTSCREEN. This is a Gaussian plume dispersion model designed as a screening technique for regulatory application to plume impaction assessments in complex terrain. CTSCREEN is a screening version of the CTDMPLUS model (see **Preferred/Recommended Models**).

Rough Terrain Diffusion Model (RTDM3.2). This is a sequential Gaussian plume model designed to estimate ground-level concentrations

in rough (or flat) terrain in the vicinity of one or more co-located point sources.

SCREEN3. This is single source Gaussian plume model which provides maximum ground-level concentrations for point, area, flare, and volume sources, as well as concentrations in the cavity zone, and concentrations due to inversion break-up and shoreline fumigation. SCREEN3 is a screening version of the ISC3 model (see **Alternative Models**). See also http://www.epa.gov/scram001/userg/screen/screen3d.pdf.

Toxic Screening Model (TSCREEN). This is a Gaussian model that implements the procedures to correctly analyze toxic emissions and their subsequent dispersion from one of many different types of possible releases for superfund sites. It contains 3 models: *SCREEN3*, PUFF, and RVD (Relief Valve Discharge). See also http://www.epa.gov/scram001/userg/screen/tscreend.pdf.

VALLEY. This is a steady-state, complex terrain, univariate Gaussian plume dispersion algorithm designed for estimating either 24-hour or annual concentrations resulting from emissions from up to 50 (total) point and area sources.

VISCREEN calculates the potential impact of a plume of specified emissions for specific transport and dispersion conditions.

See also http://www.epa.gov/scram001/dispersion_screening.htm#valley.

Related Programs

The programs and utilities listed here are used in support of some of the **preferred/recommended, alternative, and screening models**. The models in this section include:

AERMAP. This is a terrain preprocessor for AERMOD. AERMAP processes commercially available Digital Elevation Data and creates a file suitable for use within an AERMOD control file. This file would contain elevation and hill-height scaling factors for each receptor in the air dispersion study. See also http://www.epa.gov/scram001/7thconf/aermod/aermapugb2.pdf.

AERSURFACE. This is a program that processes land use data to determine the surface characteristics that should be used in AERMET. See also http://www.epa.gov/scram001/metobsdata_procaccprogs.htm#aermet.

Building Profile Input Program (BPIP). BPIP is a PC-based program designed to incorporate the concepts and procedures expressed in the Good Engineering Practice (GEP) technical support document, http://www.epa.gov/scram001/guidance/guide/gep.pdf, building downwash guidance, and other related references that correctly calculate building heights (bh) and projected building widths (pbw) for simple, multi-tiered, and groups of structures. This program is often used with the ISC3 model (see **Alternative Models**). See also http://www.epa.gov/scram001/userg/relat/bpipd.pdf.

Building Profile Input Program for PRIME (BPIPPRM). BPIPPRM is the same as BPIP but includes an algorithm for calculating downwash values for input into the PRIME algorithm which is contained in such models as AERMOD. The input structure of BPIPPRM is the same as that of BPIP and is often used with the ISC3 model. See also http://www.epa.gov/scram001/7thconf/iscprime/useguide.pdf.

Calms Processor (CALMPRO). CALMPRO is a meteorological processor which provides consistent application of handling calms by setting the wind direction of the calm hour to the last reported wind direction and the wind speed to 1 m/s.

CHAVG. CHAVG is a post-processor program for computing running averages (averages that begin each hour and overlap) and end-to-end averages (averages that do not overlap) from hourly concentrations files.

CONCOR. CONCOR is a program for converting latitude/longitude coordinates to UTM or UTM coordinates to latitude/longitude. See also http://www.epa.gov/scram001/dispersion_related.htm.

The Emissions Modeling System for Hazardous Pollutants (EMS-HAP). EMS-HAP is an emissions processor that performs the steps needed to process an emission inventory for input into the ASPEN model or the ISCST3 model (see **Alternative Models**). EMS-HAP is written in the SAS programming language and is designed to run on any UNIX workstation. See also http://www.epa.gov/scram001/userg/other/emshapdescv3.pdf.

Photochemical Modeling

Photochemical air quality models have become widely recognized and routinely utilized tools for regulatory analysis and attainment demonstrations by assessing the effectiveness of control strategies. These photochemical models are large-scale air quality models that simulate the changes of pollutant concentrations in the atmosphere using a set of mathematical equations characterizing the chemical and physical processes in the atmosphere. These models are applied at multiple spatial scales from local, regional, national, and global.

There are two types of photochemical air quality models commonly used in air quality assessments: the Lagrangian trajectory model that employs a moving frame of reference, and the Eulerian grid model that uses a fixed coordinate system with respect to the ground. Earlier generation modeling efforts often adopted the Lagrangian approach to simulate the pollutants formation because of its computational simplicity. The disadvantage of Lagrangian approach, however, is that the physical processes it can describe are somewhat incomplete. Most of the current operational photochemical air quality models have adopted the three-dimensional Eulerian grid modeling mainly because of its ability to better and more fully characterize physical processes in the atmosphere and predict the species concentrations throughout the entire model domain. Additional photochemical air quality models include:

Community Multi-scale Air Quality (CMAQ). The primary goals for the CMAQ modeling system are to improve 1) the environmental management community's ability to evaluate the impact of air quality management practices for multiple pollutants at multiple scales and 2) the scientist's ability to better probe, understand, and simulate chemical and physical interactions in the atmosphere.

The CMAQ modeling system is supported by the Community Modeling and Analysis System (CMAS) Center, http://www.cmascenter.org/. The CMAQ model includes state-of-the-science capabilities for conducting urban to regional scale simulations of multiple air quality issues, including tropospheric ozone, fine particles, toxics, acid deposition, and visibility degradation. See also http://www.epa.gov/asmdnerl/CMAQ/cmaq_model.html.

Comprehensive Air quality Model with Extensions (CAMx). CAMx is an Eulerian photochemical dispersion model that allows for integrated "one-atmosphere" assessments of gaseous and particulate air pollution. The CAMx model simulates air quality over many geographic scales. The model treats a wide variety of inert and chemically active pollutants, including ozone, particulate matter, inorganic and organic PM2.5/PM10, and mercury and other toxics. CAMx also has plume-in-grid and source apportionment capabilities. See also http://www.camx.com//.

Regional Modeling System for Aerosols and Deposition (REMSAD). REMSAD was designed to calculate the concentrations of both inert and chemically reactive pollutants by simulating the physical and chemical processes in the atmosphere that affect pollutant concentrations over regional scales. It includes those processes relevant to regional haze, particulate matter and other airborne pollutants, including soluble acidic components and mercury. See also http://remsad.saintl.com/overview.htm; and http://remsad.saintl.com/.

The Variable Grid Urban Airshed Model® (UAM-V®) System. The UAM-V® Photochemical Modeling System was a pioneering effort in photochemical air quality modeling in the early 1970s and has been used widely for air quality studies focusing on ozone. It is a three-dimensional photochemical grid model designed to calculate the concentrations of both inert and chemically reactive pollutants by simulating the physical and chemical processes in the atmosphere that affect pollutant concentrations. This model is typically applied to model air quality "episodes" — periods during which adverse meteorological conditions result in elevated ozone pollutant concentrations. See also http://uamv.saintl.com/overview.htm; http://uamv.saintl.com/info.htm: and http://uamv.saintl.com/.

Receptor Modeling

Receptor models are mathematical or statistical procedures for identifying and quantifying the sources of air pollutants at a receptor location. Unlike photochemical and dispersion air quality models, receptor models do not use pollutant emissions, meteorological data and chemical transformation mechanisms to estimate the contribution of sources to receptor concentrations. Instead, receptor models use the chemical and physical characteristics of gases and particles measured at source and receptor to both identify the presence of and to quantify source contributions to receptor concentrations. These models are therefore a natural complement to other air quality models and are used as part of State Implementation Plans (SIPs) for identifying sources contributing to air quality problems. The EPA has developed

the Chemical Mass Balance (CMB) and UNMIX models as well as the Positive Matrix Factorization (PMF) method for use in air quality management. CMB fully apportions receptor concentrations to chemically distinct source-types depending upon the source profile database, while UNMIX and PMF internally generate source profiles from the ambient data.

Chemical Mass Balance (CMB). The EPA-CMB Version 8.2 uses source profiles and speciated ambient data to quantify source contributions. Contributions are quantified from chemically distinct source-types rather than from individual emitters. Sources with similiar chemical and physical properties cannot be distinguished from each other by CMB. See also http://www.epa.gov/scram001/receptor_cmb.htm.

UNMIX. The EPA UNMIX model "unmixes" the concentrations of chemical species measured in the ambient air to identify the contributing sources. Chemical profiles of the sources are not required, but instead are generated internally from the ambient data by UNMIX, using a mathematical formulation based on a form of factor analysis. For a given selection of species, UNMIX estimates the number of sources, the source compositions, and source contributions to each sample. See also http://www.epa.gov/nerl/research/2004/g1-6.html.

Positive Matrix Factorization (PMF). The PMF technique is a form of factor analysis where the underlying co-variability of many variables (e.g., sample to sample variation in PM species) is described by a smaller set of factors (e.g., PM sources) to which the original variables are related. The structure of PMF permits maximum use of available data and better treatment of missing and below-detection-limit values. Also available is a document which discusses the PMF methodology: "A Guide to Positive Matrix Factorization", http://www.epa.gov/ttn/amtic/files/ambient/pm25/workshop/laymen.pdf.

AIR QUALITY STANDARDS. Maximum legal concentration limits of air pollutants averaged over specified time periods.

These are prescriptive. If the actual measured concentration averaged over time exceeds the legal threshold, then the event is called an exceedence. Regulations often allow a limited number of exceedences each year, with fines or penalties imposed for too many exceedences. Regions with too many exceedences are required to develop plans to improve the air quality, for example, by changing automobile fuels and gas-station equipment or increasing the use of mass transportation. In the United States, the standards are called National Ambient Air Quality Standards (NAAQS), http://www.epa.gov/air/criteria.html. Primary standards are designed to protect human health. Secondary standards are designed to protect crops, animals, structures, and commerce. In Canada, and the United Kingdom these legal thresholds are called National Air-Quality Objectives. See also http://www.hc-sc.gc.ca/ewh-semt/pubs/air/naaqo-onqaa/index_e.html; and http://www.cravendc.gov.uk/Craven/Business/EnvironmentalProtection/AirPollution/AirQuality/NationalAirQualityObjectives/. Three levels of standards exist within these objectives. In ascending order of concentration limit they are Maximum Desirable Level, Maximum Acceptable Level, and Maximum Tolerable Level.

See also **Air Quality Criteria**.

AMS

AIRSHIP. See **Dirigibles and Airships**.

AIR SPEED. See **Meteorology**.

AIRSPEED INDICATOR. Many air-data flight instruments operate from static or "pitot" pressure, or both. These pressures are usually obtained from a pitot-static tube of the type shown in Fig. 1. On the smooth side of the pitot tube, the pressure differs little from that of undisturbed air, and slots placed there provide a source of static pressure. Tubes usually are electrically heated to melt off any ice that might form and which would partly or fully seal off the openings and give erroneous readings in various air-data instruments. See Fig. 2. The difference between the pitot pressure and static pressure is a measure of *indicated airspeed*. Airspeed indicators are calibrated in knots (nautical mph) under standard pressure (29.92 inches of mercury) and temperature (59 °F). A relationship between pressure difference and airspeed in knots is given in Table 1. See also **Pitot Tube**.

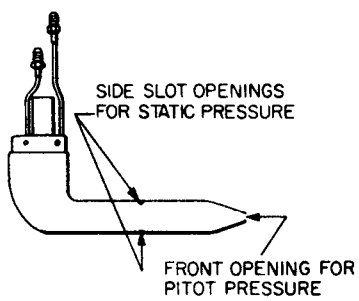

Fig. 1. Pitot tube of type used in aircraft.

True-Airspeed Indicator. This instrument is primarily used for navigation. The measurement is a function not only of difference in pitot and static pressure, but also of temperature. In effect, a true-airspeed indicator (Fig. 3) is a computer operating on a rather complex relationship of two pressures and air temperature to give the correct indication. The relationship is

$$V = 38.94 \frac{M\sqrt{T_1}}{\sqrt{1 + 0.2KM^2}}$$

where V = true airspeed, knots; T_1 = indicated air temperature, Kelvin; K = recovery factor of temperature probe (usually 1.00 or slightly less); and M = Mach number.

Another approach is to use the speed of an air turbine as a measure of true airspeed, the intake pressure to the turbine being static pressure and the output being balanced to pitot pressure.

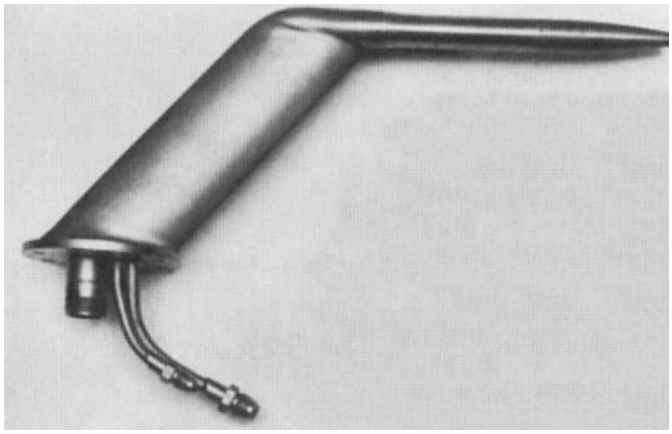

Fig. 2. Electrically heated pitot static tube.

TABLE 1. AIRSPEED VERSUS DIFFERENTIAL PRESSURE AT STANDARD TEMPERATURE AND PRESSURE

Indicated Airspeed, Knots	Differential Pressure, in Hg	Indicated Airspeed, Knots	Differential Pressure, in Hg
0	0.000000	400	8.3973
10	0.004795	450	10.8837
20	0.019185	500	13.7967
30	0.043179	550	17.1859
40	0.076793	600	21.1088
50	0.1200	650	25.6316
60	0.1729	700	30.8159
70	0.2355	750	36.6276
80	0.3079	800	43.0092
90	0.3901	850	49.9241
100	0.4821	900	57.3481
125	0.7557	950	65.2644
150	1.0924	1,000	73.6613
175	1.4938	1,050	82.5302
200	1.9616	1,100	91.8649

250	3.1045	1,200	111.9136
275	3.7845	1,250	122.6210
300	4.5407	1,300	133.7805
350	6.2949	1,320	138.3706

Source: Battelle Memorial Institute.

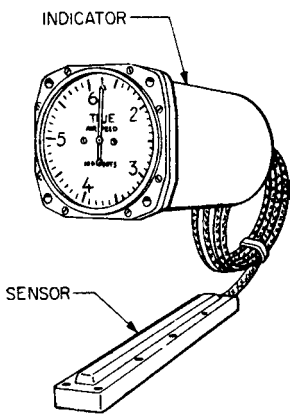

Fig. 3. True-airspeed indicator.

Machmeter. The ratio of true airspeed to the velocity of sound is called *Mach number*. The safe top speed of fast aircraft is usually expressed in terms of Mach number and is indicated on a Machmeter. See Fig. 4. This is also a mechanical computer which operates on the relationship of static and pitot pressures to give the proper indication.

Fig. 4. Combined true-airspeed and Mach number computer indicator.

AIR TOXINS. See **Meteorology**.

AITKEN DUST COUNTER. An instrument developed by John Aitken for determining the dust content of the atmosphere. In operation, a sample of air is mixed, in an expandable chamber, with a larger volume of dust-free air containing water vapor. Upon a sudden expansion, the chamber cools adiabatically below its dewpoint, and the droplets form with the dust particles as nuclei (Aitken nuclei). A portion of these droplets settle on a ruled plate in the instrument and are counted with the aid of a microscope. Also called *Aitken nucleus counter*.

AITKEN NUCLEI. The microscopic particles in the atmosphere that serve as condensation nuclei for droplet growth during the rapid adiabatic expansion produced by an Aitken dust counter. These nuclei, are both solid and liquid particles with diameters on the order of tenths of microns or smaller. Because of the excessive supersaturations that accompany expansions of the air sample in an Aitken dust-counter, the nucleus spectrum observed with this instrument does not correspond to that observed in natural cloud condensation processes, where supersaturations larger than one per cent over water are probably rare. On the other hand, Aitken nuclei play an important role in determining the local electrical conductivity of the air, because they capture small ions, becoming large ions with much lower mobility in the earth's fair-weather electric field. In air containing large numbers of Aitken nuclei, the small ion population is small, the large ion population is large, and the air conductivity is low. Either nucleus may also be a protoparticle for larger particles such as cloud condensation nuclei, the subset of Aitken nuclei responsible for the formation of cloud droplets.

ALABANDITE. Manganese sulfide, MnS. Associated with pyrite, sphalerite, and galena in metallic sulfide vein deposits.

ALABASTER. A fine-grained variety of the mineral gypsum, formerly much used for vases and statuary. It is usually white in color or may be of other light, pleasing tints.

The word alabaster is derived from the Greek name for this substance. See also **Gypsum**.

ALASKA CURRENT. See **Ocean Currents**.

ALASKAN STREAM. See **Ocean Currents**.

ALBEDO (Astronomy). A term used to indicate the reflecting power of an object. Technically defined, albedo (often referred to as the Bond albedo) is the ratio of the radiation reflected from an object to the total amount incident upon it. Thus,

$$A = pq$$

where p is the ratio of the brightness at the phase angle of zero to the brightness of a perfectly diffusing disk under the same conditions, and where q is a factor representing the phase law. For example, the albedo of

the moon is 0.068, which means that the moon reflects that fraction of the sunlight incident upon it. The value of the albedo of a planet is a measure of the quantity of atmosphere that surrounds the object. The higher the albedo, the thicker the atmospheric layer. In the case of objects without atmosphere, as in the case of the moon, the albedo, combined with the color of the reflected light, may be used to make estimates of the character of the material making up the surface of the object.

ALBEDO (Physics). In nuclear physics, the albedo is the ratio of the neutron current density out of a (non-source) medium to the neutron current density into it. In cosmic ray physics, albedo refers to those energetic, charged secondary cosmic rays that move generally upward. Because some of these particles go far into the upper atmosphere and return to the earth's surface (due to the effect of the earth's magnetic field), measurements of primary cosmic radiation must be corrected for the contribution of the albedo particles.

ALBERTA CLIPPER. An Alberta clipper is a low pressure system that is often fast-moving, has low moisture content, and originates in western Canada (in or near Alberta province). In the wintertime, it may be associated with a narrow, but significant band of snowfall and typically affects portions of the plains states, Midwest, and East Coast of the U.S.

Whether the storm is crossing Canadian territory or that of the United States, the effect is largely the same. The storms sweep in at high speed over whatever land they encounter, usually bringing with them sharp cold fronts and drastically lower temperatures. It is not uncommon for an Alberta clipper to cause temperatures to drop by 30 °F (16 °C) in as little as 10 to 12 hours. Also, the storms almost always bring biting winds with them, only increasing the effect of the newly lower temperatures. Winds in advance and during an Alberta clipper are frequently as high as 35 to 45 mph (56 to 72 km/h). As if this were not enough, Alberta clippers also tend to bring snow with them, although since the temperatures are lower the snowflakes are smaller and therefore accumulations are less. A typical Alberta clipper will leave approximately 2 inches (51.2 mm) of snow in its wake, but exceptionally powerful ones or those acting with help from other meteorological sources, i.e., the Gulf of Mexico, can produce up to 8 inches (200 mm) of snow. In winter, Alberta clippers can occur somewhat frequently, two occurring in the same week for several weeks at a time would not be considered unusual.

ALBERTA LOW. A low that originates centered on the eastern slope of the Canadian Rockies in the province of Alberta, Canada. Formerly, it was thought that such lows actually originated (more or less independently) over this location. It is now recognized that depressions moving inland from the Pacific are the actual parent systems. Alberta lows appear as these systems enhance, or are enhanced by, the dynamic trough that is a typical, almost semipermanent, feature of this region. See also **Alberta Clipper**.

ALBERTITE. An oxygenated hydrocarbon that differs from asphaltum slightly in that it is not completely soluble in turpentine, nor can it be perfectly fused. Specific gravity, 1.097, pitchy luster, dark brown to black color. Occurs in veins from 1 to 16 feet (0.3 to 5 meters) wide in the Albert Shale of Albert County, New Brunswick.

ALBINISM. Absence of pigmentation. The condition has been noted in occasional individuals of many species which are normally pigmented, including humans. In some cases the term is applied to a partial lack of pigment, as in the white form of certain normally yellow butterflies; in this form the black markings characteristic of the species are fully developed. In contrast, the total lack of pigment in albino birds and mammals is shown by the pink eyes. In these organs pigment is functionally important but the albino fails to develop it, hence the color of the blood is seen through the tissues. Albinism in humans is known to be inherited as a recessive to normal pigmentation. The term is also applied to normally green plants that fail to develop chlorophyll. As in humans, albinism is inherited as a simple recessive. Albino plants die as soon as food is exhausted from the seed. Partial albinism in plants is known as variegation.

Skin pigmentation and tanning are related to the amount of melanin in epidermal melanosomes. In the latter, tyrosine is oxidized to dopa and dopaquinone by the enzyme *tyrosinase*. The intermediate compounds polymerize to form the brown-black melanin pigment. Malfunction of this process, rather than resulting in what is considered normal pigmentation for a given species, may result in hypo- or hyperpigmentation.

Albinism results from a deficiency in melanin formation and is a form of hypopigmentation. *Hypomelanosis* may result from trauma or certain infections, including leprosy, syphilis, and pinta. *Oculocutaneous albinism*, involving white skin and hair, photophobia, and nystagmus, is noted at birth. This is the result of an inborn error of metabolism, inherited as an autosomal recessive trait. The occurrence is rare, estimated at one case in 20,000 individuals. In the most common form of albinism, the individual cannot synthesize tyrosinase. Individuals with photophobia should use sunglasses and essentially avoid exposure to the sun. Medications incorporating sun screening substances can be used.

A condition known as *vitiligo* is encountered in about one percent of individuals. It has been suggested that vitiligo is probably inherited as an autosomal dominant characteristic. Areas of macular depigmentation occur on the extremities, face, neck, and skin folds. Bilateral symmetry is common. Although vitiligo usually is found in individuals who otherwise have normal health, some patients with vitiligo are prone to such disorders as thyroid disease (hyperthyroidism, Grave's disease, thyroiditis), Addison's disease, pernicious anemia, and alopecia areata. There may be an association of vitiligo with diabetes. A number of relatively useful remedial treatments are available to alleviate the cosmetic defects of vitiligo, including avoidance of exposure to the sun, use of sunscreens, the topical or oral use of methoxsalen (photosensitizing drug), triosalen, followed by controlled exposure to sunlight or longwave ultraviolet light.

ALBUMIN. An albumin is a member of a class of proteins which is widely distributed in animal and vegetable tissues. Albumins are soluble in water and in dilute salt solutions, and are coagulable by heat.

Albumin is of great importance in animal physiology; in man it constitutes about 50% of the plasma proteins (blood) and is responsible to a great extent for the maintenance of osmotic equilibrium in the blood. The high molecular weight (68,000) of the albumin molecule prevents its excretion in the urine; the appearance of albumin may indicate kidney damage. See **Kidney and Urinary Tract**.

ALCHEMY. The predecessor of chemistry, practiced from as early as 500 BC through the 16th century. Its two principal goals were transmutation of the baser metals into gold and discovery of a universal remedy. Modern chemistry grew out of alchemy by gradual stages.

ALCOHOL. A term commonly used to designate ethyl alcohol or ethanol. See **Ethyl Alcohol**. Also a class of organic compounds. See **Alcohols**.

ALCOHOLATE. Replacement of the hydrogen in the hydroxyl group of an alcohol by a metal, particularly a metal that forms a strong base, results in formation of an alcoholate. An example is sodium ethylate, C_2H_5ONa.

ALCOHOLISM. Alcoholism is a disease that results from neuroadaptive processes induced by repeated alcohol exposure and controlled by genetic factors. Although treatment for alcoholism is inadequate, current research suggests that new therapies will arise from understanding the genes and biochemical mechanisms that regulate alcohol consumption and craving.

Alcoholism is the most common form of drug abuse and a major public health problem worldwide. About 7–10% of adults in the United States suffer from alcohol dependence and over 20% of hospitalized patients have a medical disorder related to heavy drinking. The annual cost of alcoholism due to medical and socioeconomic problems is at least $100 billion in the United States. Recent advances in neuroscience make it possible to identify neural pathways and molecular processes involved in the pathophysiology of alcoholism. These studies reveal a key role for the mesolimbic dopaminergic pathway and the amygdala in mechanisms of reward and alcohol abuse. In addition, ethanol modulates hormone- and neurotransmitter-activated signal transduction, leading to short-term changes in neuronal function and long-term changes in neural gene

expression. These changes appear to underlie the development of alcohol tolerance, dependence and craving, and may also contribute to some of the medical complications of alcoholism such as cirrhosis of the liver.

Clinical Syndrome of Alcoholism

Alcoholism is a chronic disease characterized by addiction to ethanol. Alcoholics crave alcoholic beverages, and with continued drinking develop tolerance to the intoxicating effects of ethanol. Upon discontinuing drinking, they develop physical signs of withdrawal, demonstrating physical dependence on ethanol. Alcoholics often seek ethanol at the exclusion of important social, occupational or recreational activities and continue to drink despite medical and socioeconomic complications. Alcoholism is distinguished from alcohol abuse, which involves recurrent episodes of intoxication (binge drinking) without physical dependence. Nevertheless, these episodes cause serious adverse economic, social, legal and health complications.

Pharmacokinetics

Ethanol is rapidly absorbed from the stomach and can be detected in the blood within a few minutes. Peak blood levels usually occur within an hour after drinking. Absorption is delayed by intake of food and accelerated by impaired gastrointestinal motility. Women have lower gastric alcohol dehydrogenase activity and consequently develop higher blood alcohol levels than men when consuming similar amounts of alcohol. Ethanol equilibrates in total body water and rapidly crosses cell membranes. Ethanol is metabolized primarily in the liver at a constant rate, about 5-gram (0.2 ounce) per hour in a 70-kilogram man (154 pound). When drinking is discontinued, blood alcohol levels fall at a rate of about 10-$\mathrm{mg\,dL^{-1}\,h^{-1}}$. An average drink contains 12-g (0.4 ounce) ethanol, thus, the rate of elimination is about one drink per hour.

At low to moderate doses, approximately 90% of ethanol is oxidized to acetaldehyde by hepatic alcohol dehydrogenase. At high ethanol concentrations, a microsomal ethanol-oxidizing system with lower affinity for ethanol also generates acetaldehyde. This system can be induced by ethanol and other drugs such as barbiturates, which accelerate hepatic metabolism of alcohol. Acetaldehyde is metabolized in the liver by aldehyde dehydrogenase to yield acetate, which is converted in peripheral tissues to acetylcoenzyme A and subsequently to carbon dioxide and water. Complete oxidation of ethanol generates 7 $\mathrm{kcal\,g^{-1}}$ and alcoholics may obtain 50% of their total caloric intake from ethanol. This can lead to nutritional deficiencies, especially of protein, folate, thiamine, niacin and pyridoxine.

Approximately half of Asians carry an allele of aldehyde dehydrogenase ($ALDH2^2$) that encodes an isozyme with reduced enzymatic activity. After drinking alcohol, affected individuals have increased blood acetaldehyde levels and experience vasodilatation, tachycardia, hot sensations and hypotension. They also report feeling intoxicated at very low doses of alcohol. Individuals expressing this isoenzyme rarely abuse alcohol. Disulfiram inhibits aldehyde dehydrogenase and causes a severe alcohol-flush reaction when taken with alcohol. It is used to deter drinking, but is not entirely effective.

Alcohol Intoxication

Clinical Features. Ethanol readily crosses the blood–brain barrier and, shortly after drinking, the concentration of ethanol in the brain is almost the same as that in blood. Intoxication develops in nonalcoholics at blood alcohol levels of 50-$\mathrm{mg\,dL^{-1}}$ and is more severe when blood levels are rising than falling. At these concentrations, most individuals experience euphoria, loss of social inhibitions and jovial behavior, but some become gloomy, belligerent or violent. Certain individuals become excessively drowsy without euphoria after drinking and describe the experience as unpleasant; they rarely abuse alcohol. Signs of mild intoxication include slurred speech, impaired cognition and mild incoordination. At higher blood ethanol levels, cerebellar and vestibular functions become severely impaired, with marked ataxia, dysarthria, nystagmus and diplopia. See also **Blood-Brain Barrier**.

Pharmacological effects of alcohol occur at millimolar concentrations, and there is no distinct receptor for ethanol that mediates its actions. Recent evidence suggests that ethanol interacts with hydrophobic domains within certain membrane proteins. Table 1 lists several neurotransmitter receptors, ion channels and transporters whose function is altered by intoxicating concentrations of ethanol. Among these, γ-aminobutyrate type A ($GABA_A$) and *N*-methyl-d-aspartate (NMDA) receptors appear to be especially important.

TABLE 1. MEMBRANE PROTEINS REGULATED BY INTOXICATING CONCENTRATIONS OF ETHANOL

Protein	Class	Effect of ethanol on function
$GABA_A$ receptor	Rceptor-gated Cl^- channel	Enhancement
NMDA receptor	Receptor-gated cation ($Ca^{2+} > NA^+$) channel	Inhibition
AMPA/kainate receptor	Receptor-gated cation channel	Inhibition
5-HT_3 receptor	Receptor-gated cation channel	Enhancement
Strychnine-insensitive glycine receptor	Receptor-gated Cl^- channel	Enhancement
Nicotinic cholinergic receptor	Receptor-gated cation channel	Inhibition
Nucleoside transporter ENT-1	Membrane transport of adenosine	Inhibition
L-type calcium channel	Voltage-gated ion channel	Inhibition
δ Opioid receptor	G protein-coupled receptor	Inhibition
Adenylate cyclase VII	G protein-coupled receptor	Inhibition

[a] AMAP, α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate; $GABA_A$, γ-aminobutyrate type A; 5-HT_3, 5-hydroxytryptamine type 3; NMDA, *N*-methyl-D-asparate; ENT1, equilibrative nucleoside transporter 1.

$GABA_A$ Receptors. The major inhibitory neurotransmitter in the nervous system is GABA. Binding of GABA to $GABA_A$ receptors activates a Cl^- current, and this response is enhanced by benzodiazepines, barbiturates, ethanol and neurosteroids. $GABA_A$ receptors in the mammalian brain appear to be pentameric membrane glycoprotein complexes of about kDa composed of subunits from six different classes, most with multiple variants (six α, three β, three γ, one δ, one ε and one θ). Most receptors in the brain are composed of α, β and γ subunits with $\alpha 1 \beta 2 \gamma 2$ being the most abundant combination. Subunit composition alters the pharmacological properties of recombinant receptors. There is considerable regional variation in subunit expression in the brain, and this may account for differences in the pharmacology of receptors in different neurons.

Intoxicating concentrations of ethanol potentiate $GABA_A$ receptor function. Benzodiazepine inverse agonists, such as the imidazobenzodiazepine Ro15-4513, reduce ethanol intoxication but cause seizures. Studies with lines of mice and rats selected for genetic differences in behavioral responses to ethanol also implicate $GABA_A$ receptors in ethanol intoxication. Long-sleep (LS) mice are more sensitive to the acute hypnotic effect of ethanol than short-sleep (SS) mice. $GABA_A$ receptors expressed from LS mice show greater enhancement of GABA-stimulated chloride flux by ethanol, whereas receptors from SS mice show the opposite response. In rats, microinjection of muscimol into the nucleus accumbens (NAc) or amygdala substitutes for ethanol in drug discrimination studies and microinjection of the competitive $GABA_A$ receptor antagonist SR 95531 into the central nucleus of the amygdala, the bed nucleus of the stria terminalis or shell of the NAc decreases ethanol self-administration suggesting that actions of ethanol at $GABA_A$ receptors in specific limbic brain regions regulate ethanol discrimination and reward.

Ethanol appears to directly interact with $GABA_A$ receptors. Analysis of $GABA_A$ receptor mutants has identified a binding pocket involving transmembrane domains 2 and 3 of the $\alpha 1$ or $\alpha 2$ subunits and transmembrane domain 2 of $\beta 1$ subunits that modulates responses to alcohols. Ethanol may also regulate $GABA_A$ receptors indirectly by stimulating the production of the neurosteroid allopregnanolone. Increases in allopregnanolone are evident min after systemic ethanol administration in rats, and levels correlate with the duration of ethanol-induced hypnosis. Inhibition of allopregnanolone synthesis reduces the anticonvulsant effect of ethanol and reverses ethanol inhibition of spontaneous activity in medial septal neurons. Thus, allopregnanolone may contribute to some effects that appear several minutes after acute ethanol administration.

N-Methyl-D-Aspartate Receptors. Excitatory synaptic activity evoked by glutamate and aspartate is mediated by ionotropic receptors that

regulate cation conductances or by metabotropic receptors that stimulate phosphoinositide hydrolysis. Ionotropic glutamate receptors have been subclassified based on activation by selective agonists into three groups: NMDA receptors, high-affinity kainate receptors and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. NMDA receptors are studied intensely as they are involved in learning and memory, and are critical for long-term potentiation (LTP) of excitatory neurotransmission, a synaptic plasticity model of learning and memory. Acute exposure to intoxicating concentrations of ethanol inhibits NMDA-activated calcium currents, which appears to contribute to behavioral features of intoxication. Ethanol also inhibits LTP, suggesting that inhibition of NMDA receptor function could explain certain cognitive defects and amnesic episodes ("blackouts") associated with severe ethanol intoxication.

Adenosine. Adenosine is a major inhibitory neuromodulator in the brain, acting through adenosine A_1 and A_2, and other receptor subtypes on neural cells. Adenosine modulates calcium channels and inhibits excitatory synaptic transmission by attenuating the release of excitatory transmitters from presynaptic nerve endings. Adenosine also acts postsynaptically to reduce cellular responses to dopamine and acetylcholine. The extracellular concentration of adenosine increases with neural activity, and inhibitors of adenosine uptake potentiate cellular responses to adenosine, suggesting that its physiological effects are terminated, in part, by reuptake into cells.

Adenosine is transported into mammalian cells by nucleoside transporters; ethanol inhibits one subtype (ENT1), resulting in accumulation of extracellular adenosine. Adenosine A1 receptors appear to mediate several of the acute intoxicating effects of ethanol such as ataxia and sedation. Adenosine receptor agonists enhance some of the intoxicating effects of ethanol, and antagonists diminish this response. Sensitivity to adenosine agonists and antagonists correlates with acute alcohol sensitivity in mice bred for differential responses to the sedating effects of ethanol, and the intoxicating effects of ethanol are exacerbated by drugs that reduce adenosine reuptake via nucleoside transporters. Also, there is cross-tolerance between ethanol and adenosine agonists after long-term exposure to either agent. This suggests the possibility that specific adenosinergic agents may be able to modify some alcohol-related behaviors.

Tolerance and Dependence

Tolerance is a reduced response to ethanol. Rapid tolerance develops after several hours of repeated drinking. At that time, an individual may appear sober at blood ethanol levels that initially caused intoxication. Rapid tolerance may be due in part to ethanol-stimulated activation of the tyrosine kinase B-fyn and subsequent tyrosine phosphorylation of NMDA receptors, leading to decreased sensitivity of NMDA receptors to inhibition by ethanol.

Chronic tolerance to alcohol occurs in alcoholics after several days of heavy drinking. The magnitude of tolerance can be striking and some individuals appear sober at blood alcohol levels of 400-mg dL^{-1}, which can be fatal in nonalcoholics. A hyperexcitable withdrawal syndrome, which is evidence of physical dependence on ethanol, develops in alcoholics who abruptly reduce or discontinue drinking. The clinical features include tremor, disordered perceptions, convulsions and hyperactivity of the sympathetic nervous system leading, in extreme cases, to increased heart rate and body temperature, profuse sweating and circulatory collapse. These manifestations arise from adaptive cellular changes during chronic ethanol exposure, which serve to maintain homeostasis in the continued presence of ethanol. During alcohol withdrawal, homeostasis is once again disturbed and a hyperexcitable state results. Repeated use of ethanol also induces an aversive emotional state that includes anxiety, irritability and unpleasant feelings (dysphoria). Alcohol consumption reduces these feelings, thereby promoting continued drinking. Many biochemical systems contribute to alcohol dependence, but alterations in $GABA_A$ receptors, NMDA receptors, voltage-gated calcium channels and cyclic adenosine monophosphate (cAMP) signal transduction appear to be particularly important.

GABA Receptors. Chronic exposure to ethanol abolishes potentiation of $GABA_A$ receptor function by ethanol. This downregulation of $GABA_A$ receptor sensitivity to ethanol may contribute to behavioral tolerance to alcohol in animals and humans following chronic ethanol exposure. There is cross-tolerance between ethanol and other drugs that activate $GABA_A$ receptors such as benzodiazepines and barbiturates. Consequently, benzodiazepines and barbiturates have proven very helpful in reducing the withdrawal symptoms that follow chronic ethanol administration.

NMDA Receptors. In contrast to downregulating $GABA_A$ receptors, chronic ethanol exposure increases the density of NMDA receptors, especially in the hippocampus. This may contribute to the generation of alcohol withdrawal seizures since MK-801, an NMDA receptor antagonist, inhibits alcohol withdrawal seizures in rodents. Ethanol-induced increases in NMDA receptors appear to confer increased sensitivity to NMDA-mediated neurotoxicity in cultured neurons and in rats injected intracerebrally with NMDA. This suggests that long-term memory deficits and neuronal cell loss in chronic alcoholics may be due, in part, to ethanol-induced upregulation of NMDA receptors.

Voltage-gated Calcium Channels. Several voltage-gated calcium channels have been identified and subdivided into six major groups (T, N, L, P, Q and R) by electrophysiological and pharmacological criteria. Chronic exposure to ethanol increases the function and density of L- and N-type channels in the brain and cultured neural cells. In the neural crest-derived cell line PC12, the increase in L channels requires protein kinase C δ(PKC δ), which is upregulated by chronic exposure to ethanol. Increases in L-type channels associated with neuronal hyperactivity during alcohol withdrawal may induce withdrawal symptoms by promoting neurotransmitter release. In PC12 cells, ethanol-induced upregulation of L-type channels persists for about an hour after ethanol is removed, coinciding with the time of greatest risk for alcohol withdrawal seizures after alcoholics stop drinking. In addition, L channel antagonists reduce tremors, seizures and mortality rate in alcohol-dependent mice and rats deprived of ethanol.

cAMP Signal Transduction. Ethanol changes receptor-mediated cAMP signal transduction in many biological preparations. Since cAMP regulates protein kinase A (PKA) activity, which in turn regulates many cellular functions including gene expression, ethanol-induced changes in cAMP levels could be responsible for many of the pleiotropic effects of ethanol. In general, brief exposure to ethanol potentiates receptor-activated cAMP formation, which in NG108-15 neuroblastoma–glioma cells and primary cultured neurons results from ethanol-mediated inhibition of adenosine transport, accumulation of extracellular adenosine and activation of adenosine A_2 receptors. This may be particularly important in the NAc, a striatal component of the mesolimbic circuit of reward and reinforcement involved in alcoholism, which has the highest concentration of A2 receptors in the brain. Chronic exposure to ethanol reduces cAMP signal transduction for several receptors coupled to the stimulatory guanine nucleotide regulatory protein, G_S, within the same cell. This heterologous desensitization of receptors correlates with a decrease in G_S α messenger RNA, protein and function. An increase in the inhibitory protein G_i can also occur. Thus, cellular tolerance to stimulatory effects of ethanol on cAMP production involves adaptive changes in G proteins that couple receptors to cAMP generation.

cAMP activates PKA. Ethanol-induced increases in cAMP are associated with activation of PKA and its translocation into the nucleus. PKA then phosphorylates the cAMP response element-binding protein (CREB), a major transcription factor that activates cAMP-dependent gene expression. Thus, ethanol-induced changes in PKA signaling ranging from increases in cAMP to gene expression probably contribute to alcohol-related behaviors such as craving, tolerance and dependence.

Craving

Dopamine. Alcoholics crave alcohol and drink excessively. In addition to psychosocial factors that influence drinking, endogenous neural systems play a key role in alcohol craving. The motivation to consume alcohol compulsively stems in part from its rewarding, pleasurable effects. The mesocorticolimbic dopaminergic system (Figure 1) has been implicated in brain mechanisms of reward and reinforcement. Dopaminergic neurons in the ventral tegmental area (VTA) project axons via the median forebrain bundle (MFB) to the NAc, amygdala and frontal cortex. Reciprocal projections from GABA neurons in the NAc project back through the MFB on to VTA neurons. Ethanol increases the firing of dopaminergic neurons. This increases dopamine release in the NAc where VTA neurons project, while dopamine receptor antagonists injected here reduce ethanol self-administration. Mice lacking dopamine D2 receptors exhibit reduced drinking. Moreover, rats chronically exposed to ethanol exhibit increased extracellular dopamine levels in the NAc. Unlike most other areas of the brain, the NAc/striatum is characterized by the coexpression of postsynaptic A2 and D2 receptors on the same neurons. Ethanol activation of A2 receptors stimulates cAMP production. Although activation of D2 receptors is thought to inhibit cAMP production, a brief exposure to

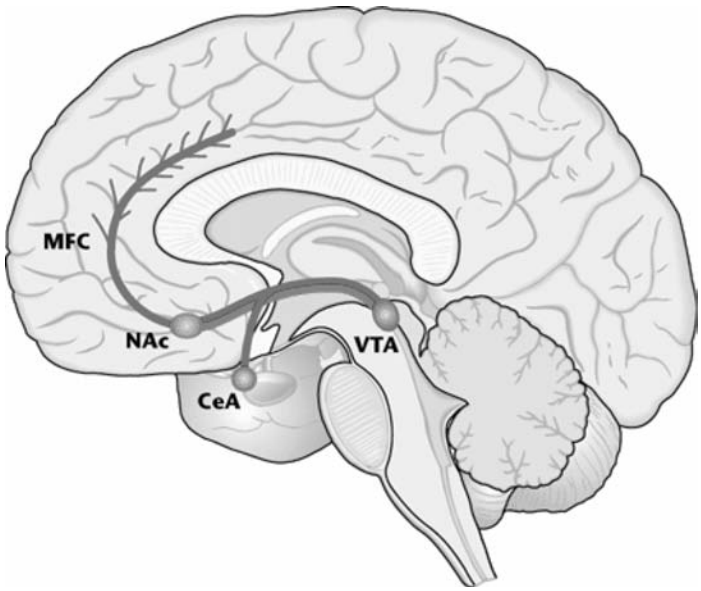

Fig. 1. Sagittal section of the human brain illustrating the major mesocorticolimbic pathways involved in drug reward and reinforcement. Red lines represent dopamine afferents from the ventral tegmental area (VTA) projecting to the amygdala, nucleus accumbens (NAc) and medial frontal cortex (MFC). The central nucleus of the amygdala (CeA) is shown because neurons there are activated in rodents during alcohol consumption, and the CeA modulates voluntary alcohol self-administration. Green lines represent afferent fibres from the NAc that project back to the VTA.

D2 agonists can mimic the effect of ethanol by increasing cAMP levels and promoting PKA translocation and cAMP-dependent gene expression. This paradoxical response is mediated by $\beta\gamma$ dimers released from Gi/o upon D2 activation. $\beta\gamma$ dimers stimulate adenylyl cyclase activity. Importantly, subthreshold concentrations of ethanol or a D2 agonist, which are ineffective when added alone, together act synergistically to activate cAMP/PKA signaling. Synergy is mediated by $\beta\gamma$ dimers that have been shown to regulate drinking behavior. Thus, direct inhibition of $\beta\gamma$ dimers bilaterally in the NAc diminishes voluntary alcohol consumption in rats. It should be noted, however, that treatment with 6-hydroxydopamine, which almost completely eliminates dopaminergic innervation of the NAc, does not reduce voluntary alcohol drinking in rats. Therefore, although mesocorticolimbic pathways contribute to reinforcing properties of alcohol, dopamine-independent pathways are also important.

Neuropeptides. Opioids bind to three classes of receptors (μ, κ and δ). Agonists of μ and δ receptors have rewarding properties and are self-administered. Ethanol acutely inhibits opiate binding to δ-opioid receptors, and prolonged exposure to ethanol increases μ and δ opioid receptors. δ-Opioid receptors can also synergize with ethanol to increase PKA signaling via $\beta\gamma$ dimers. Antagonists of μ- and δ-opioid receptors reduce alcohol consumption in experimental animals, possibly by interfering with dopamine release in the NAc. In alcoholics, naltrexone, an opioid receptor antagonist with slight selectivity for μ receptors, helps alcoholics to maintain abstinence. In several clinical trials, naltrexone, in combination with counseling, significantly reduced craving for alcohol in abstinent alcoholics, with a 50% reduction in the relapse rate.

Neuropeptide Y (NPY) is a 36-amino-acid peptide that modulates feeding, seizure threshold, anxiety and sensitivity to some sedative–hypnotic drugs. NPY activates cAMP signaling. Genetic linkage analysis of rats selectively bred for alcohol preference has identified a chromosomal region that includes the NPY gene. These rats have lower levels of NPY in several brain regions compared with alcohol-nonpreferring rats. NPY-deficient mice have recently been generated and show increased anxiety and susceptibility to seizures. They also drink alcohol excessively and are less sensitive to its sedating effects. In contrast, transgenic mice that overexpress NPY show reduced ethanol preference and are more sensitive to the sedative effects of ethanol. These results provide evidence that NPY modulates ethanol consumption and sensitivity to ethanol intoxication in a reciprocal fashion. A reciprocal relationship between acute sensitivity to alcohol and alcohol consumption has also been observed in PKC ε-deficient mice, humans carrying the *ALDH2*[2] allele and sons of alcoholics who later develop alcoholism. These findings lend support to the idea that heightened sensitivity to the acute effects of ethanol is aversive and deters further alcohol consumption. That PKA and PKC may be involved in these responses suggests targets for new drugs to treat alcoholism.

NMDA Receptors. Glutamate acting at NMDA receptors appears to inhibit dopamine release in the NAc, whereas NMDA receptor antagonists given systemically increase dopamine release in this region. Firing rates of spontaneously active dopaminergic VTA neurons are reduced during ethanol withdrawal in association with a decrease in dopamine release in the NAc. This can be reversed by treatment with ethanol or the NMDA antagonist MK-801. This suggests that acute and chronic actions of ethanol at NMDA receptors modulate dopamine release in the NAc and may play a role in the rewarding properties of ethanol.

GABA Receptors. Administration of ethanol leads to activation of GABA-containing neurons in the central nucleus of the amygdala. Injection of a $GABA_A$ receptor antagonist into this region reduces ethanol self-administration in rats. Injection of the $GABA_A$ receptor agonist muscimol into the NAc also terminates ethanol self-administration. These results suggest that GABA acting at $GABA_A$ receptors in the central nucleus of the amygdala and the NAc modulates ethanol self-administration.

Serotonin. Serotonin (5-hydroxytryptamine, 5-HT) also appears to modulate ethanol reinforcement since serotonin reuptake inhibitors have been shown to reduce ethanol intake in some studies. Recent evidence implicates specific serotonin receptors in ethanol self-administration. Ethanol enhances activation of serotonin $5\text{-}HT_3$ receptors, which in turn promote dopamine release in the NAc. Antagonists of $5\text{-}HT_3$ receptors reduce ethanol-induced dopamine release in the NAc and decrease voluntary ethanol intake in experimental animals. Antagonists of $5\text{-}HT_{2C}$ receptors also decrease alcohol consumption in rodents. However, mutant mice lacking $5\text{-}HT_{1B}$ receptors voluntarily consume almost twice as much alcohol as wild-type littermates. Taken together, these results suggest that $5\text{-}HT_{1B}$ but not $5\text{-}HT_{2C}$ or $5\text{-}HT_3$ receptors may contribute to the inhibitory effects of serotonin reuptake blockers on ethanol consumption.

Protein Kinase C. Craving is a learned activity resulting from previous experience with an addictive drug. It has been proposed that development of craving requires plastic changes in synaptic function and structure similar to those involved in learning and memory. In several brain regions, chronic exposure to ethanol stimulates growth of dendrites and axons (neurites). In the neural cell line PC12, ethanol markedly enhances neurite outgrowth stimulated by nerve growth factor or basic fibroblast growth factor. This process involves increased stimulation of mitogen-activated protein kinases and is mediated by ethanol-induced increases in PKC ε. Mice lacking PKC ε are more sensitive to acute ethanol intoxication and consume nearly 75% less alcohol than wild-type littermates, providing evidence that PKC ε influences voluntary ethanol consumption, perhaps by promoting alcohol-induced neural plasticity. Thus, PKC ε may play a key role in ethanol reinforcement. This may be related to PKC ε regulation of $GABA_A$ receptors since mice lacking PKC ε also show increased behavioral and biochemical responses to the acute effects of ethanol and other drugs that are positive allosteric activators of $GABA_A$ receptors.

Regulation of Gene Expression

Ethanol-induced changes in second messengers and protein kinase activities could produce long-term alterations in cellular function by altering gene expression. Changes in gene expression in turn could contribute to alcohol tolerance, dependence, craving and neurotoxicity. Therefore, investigators have begun to search for ethanol-induced changes in gene expression in the nervous system that might underlie adaptive responses to ethanol and neurotoxic disorders related to heavy drinking. Several proteins whose abundance is altered by ethanol include δ-opioid receptors, L-type calcium channels, PKC δ, PKC ε, tyrosine hydroxylase, several α subunits of $GABA_A$ receptors and subunits of NMDA receptors. In some cases, ethanol appears to regulate the abundance of critical proteins by altering gene expression, whereas in others protein trafficking is affected, possibly due to ethanol-induced increases in expression of molecular chaperones. Specific sequences in the promoter region of ethanol-responsive genes appear to be required for regulation of transcription by ethanol, suggesting that families of ethanol-responsive genes may be regulated by common molecular mechanisms. Also, ethanol-induced translocation of

PKA C α and other kinases could alter the phosphorylation state of transcription factors such as CREB, leading to changes in gene expression. These findings open new avenues for potential therapy of alcoholic-related medical disorders and for identification of candidate genes in alcoholism.

Genetics of Alcoholism

Genetic factors play a role in the development of alcoholism. Approximately 16–26% of fathers and 2–6% of mothers of alcoholics also are alcohol dependent. Identical twins have a higher concordance of alcoholism than fraternal twins, even when environmental factors, such as the greater frequency of social contact between identical twins, are taken into account. Among alcoholics with severe alcohol-related behavioral or medical complications, adoptees have a 2.5 times greater chance of developing alcoholism if at least one biologic parent is an alcoholic. Moreover, this risk of alcohol dependence and alcohol abuse is about 3-fold higher in sons and daughters of alcoholics, even when offspring are adopted away in early life. Estimates from twin studies suggest that genetic influences contribute overall to 60% of the risk of developing alcohol use disorders.

The genetic component of alcoholism vulnerability appears to be related to at least four factors: allelic variants of alcohol metabolizing enzymes; high levels of impulsivity or disinhibition; comorbid psychiatric disorders such as schizophrenia and bipolar disease; and a low level of response (LR) to alcohol. Low LR can be determined by observing a reduced effect of ethanol on self-rated subjective responses and on objective measures such as balance and blood cortisol or prolactin levels at a given blood ethanol concentration. Longitudinal studies of subjects evaluated for LR earlier in life have reported a higher rate of future alcoholism and alcohol abuse among males with low LRs. Two studies have identified regions on chromosomes 1, 2, 9, 10, 11, 21 and 22 with possible linkage to low LR for alcohol. The underlying genes have yet to be identified. In rodents, genetic mapping of quantitative trait loci is being used to identify chromosomal locations of genes that influence alcohol-related behaviors. An inverse association between LR and alcohol preference has been observed in some inbred strains of mice and rats but the genes responsible have not yet been identified. Several knockout mouse lines have been generated that demonstrate increased LR and reduced preference, or low LR and increased preference relative to wild-type littermates. The human homologues for some of these genes lie within loci identified in human linkage studies of alcoholism susceptibility or low LR to ethanol, and include PKC ε, neuropeptide Y, the NPY-1 receptor, Gαs and the $GABA_A$ receptor $\alpha 1$ subunit. Genetic studies utilizing well-characterized invertebrate systems may also uncover genes conserved in flies and humans that regulate responses to ethanol. *Drosophila* exhibit alcohol intoxication, tolerance and withdrawal responses, and mutant flies with altered cAMP signal transduction and genetically induced increases in acute sensitivity to ethanol and ethanol tolerance have been isolated. Studies such as these should help in the quest for candidate genes that control responses to alcohol.

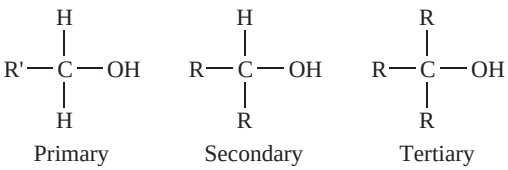
ALCOHOLS. The alcohols may be regarded as hydrocarbon derivatives in which the hydroxyl group (OH) replaces hydrogen on a saturated carbon. Alcohols are classified as *primary*, *secondary*, or *tertiary*, according to the number of hydrogen atoms that are bonded to the carbon atom with the hydroxyl substituent. Alcohols also may be regarded as alkyl derivatives of water. Thus, alcohols with a small hydrocarbon group tend to be more like water in properties than a hydrocarbon of the same number. Alcohols with a large hydrocarbon group are found to have physical properties similar to a hydrocarbon of the same structure. Some comparisons are given in Table 1. Structures are summarized by:



where $R' = H$, alkyl, aryl; $R =$ alkyl, aryl.

In addition to the basic classification as primary, secondary, or tertiary, alcohols may be further grouped according to other structural features. *Aromatic alcohols* contain an aryl group attached to the carbon having the hydroxyl function; *aliphatic alcohols* contain only aliphatic groups. The prefix *iso* usually indicates branching of the carbon chain.

Alcohols containing two hydroxyl groups are called *dihydric alcohols* or *glycols*. Ethylene glycol, $HOCH_2CH_2OH$, trimethylene glycol, $HOCH_2CH_2CH_2CH_2OH$, and 1,4-butanediol are examples of industrially important glycols. Glycerol, $HOCH_2CHOHCH_2OH$, has three hydroxyl groups per molecule and is a *trihydric* alcohol. Physical properties of alcohols containing more than one hydroxyl group can be estimated by considering the number of carbons for each hydroxyl group as in the case of simple alcohols.

Reactions of Alcohols. Alcohols undergo a large number of reactions. However, these reactions may be grouped into a few general types. Reactions of alcohols may involve the O–H or C–O bonds. Ester formation and salt formation are examples of the former class, while conversion to halides is an example of the latter type.

–O–H Bond Cleavage

(1) $ROH + CH_3COOH \overset{H_+}{\rightleftharpoons} CH_3COOR + H_2O$

TABLE 1. COMPARISON OF PHYSICAL PROPERTIES OF ALCOHOLS AND HYDROCARBONS

Alcohol	Hydrocarbon	Formula	Properties
Methanol		CH_3OH	Liquid, water soluble, bp. 65 °C
	Methane	$CH_3–H$	Gas, water insoluble
Ethanol		CH_3CH_3OH	Liquid, water soluble, bp. 78.5 °C
	Ethane	$CH_3CH_2–H$	Gas, water insoluble
Tetradecanol		$CH_3\ (CH_3)_{12}CH_2OH$	Liquid, water insoluble, bp. 263.2 °C
	Tetradecane	$CH_3(CH_2)_{12}CH_2–H$	Liquid, water insoluble, bp. 253.5 °C

(2) $ROH + K \longrightarrow RO^{-}K^{+} + \frac{1}{2}\ H_2$

C–O Bond Cleavage

(3) $RCH_2OH + HCl \xrightarrow[170\,^{\circ}C]{ZnCL_2} RCH_2Cl + H_2O$

Many industrially important substitution reactions of alcohols are conducted in the vapor phase over a catalyst. Only primary alcohols give satisfactory yields of product under these conditions.

(4) $CH_3OH + H_2S \xrightarrow{K_2WO_4} CH_3SH + H_2O$

(5) $RCH_2OH + (CH_3)_2NH \xrightarrow{Al_2O_3} RCH_2N(CH_3)_2 + H_2O$

Production of Alcohols. Lower alcohols (amyl and below) are prepared by (a) hydrogeneration of carbon monoxide (yields methanol), (b) olefin hydration (yields ethanol, isopropanol, secondary and tertiary butanol), (c) hydrolysis of alkyl chlorides, (d) direct oxidation, and (e) the OXO process.

(6) $C{=}O + 2\ H_2 \longrightarrow CH_3OH$

(7) $CH_3CH{=}CH_2 + H_2O \xrightarrow{H^+} CH_3CHOHCH_3$

(8) $C_5H_{11}Cl + H_2O \longrightarrow \underset{\text{(mixture of isomers)}}{C_5H_{11}OH}$

Most higher alcohols (hexanol and higher) and primary alcohols of three carbons or more are synthesized by one of four general processes, or derived from a structurally related natural product. See **Organic Chemistry**.

The OXO Process. An olefin may be hydroformylated to a mixture of aldehydes. The aldehydes are readily converted to alcohols by hydrogenation. Many olefins from ethylene to dodecenes are used in the OXO reaction. OXO alcohols are typically a mixture of linear and methyl branched primary alcohols.

(9) $RCH = CH_2 + CO + H_2 \longrightarrow [RCH_2CH_2CHO + RCH(CHO)CH_3]$

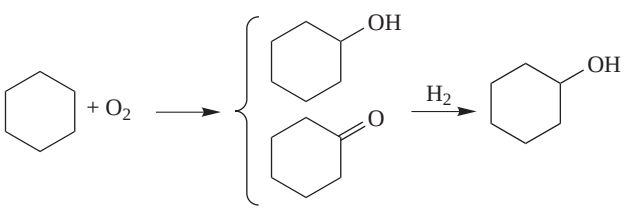
Aldol Condensation. Aldehydes may also be dimerized by an aldol condensation reaction to give a branched unsaturated aldehyde. This may be converted to a branched alcohol by hydrogenation.

(10) $2\ CH_3CH_2CH_2CHO \longrightarrow$

$$CH_3CH_2CH_2CH{=}\underset{\displaystyle C_2H_5}{\underset{|}{C}}CHO \xrightarrow{H_2} CH_3(CH_2)_3\ \underset{\displaystyle C_2H_5}{\underset{|}{C}}HCH_2OH$$

Alcohols from an aldol reaction may be linear if acetaldehyde is a reactant, but usually aldol alcohols are branched primary alcohols. An aldol condensation sometimes is done with an OXO reaction. The combined process is called the ALDOX process.

Oxidation of Hydrocarbons. Using air, the oxidation of hydrocarbons generally results in a mixture of oxygenated compounds and is not a useful synthesis of alcohols except under special circumstances. Cyclohexanol may be prepared by air oxidation of cyclohexane inasmuch as only one isomer can result.



The yield of alcohol from normal paraffin oxidation may be improved to a commercially useful level by oxidizing in the presence of boric acid.

(12) $3\ RH + \frac{3}{2}\ O_2 + H_3BO_3 \longrightarrow (RO)_3B + 3\ H_2O$

(13) $(RO)_3B + 3\ H_2O \longrightarrow H_3BO_3 + 3\ ROH$

A borate ester is formed which is more stable to further oxidation than the free alcohol. This is easily hydrolyzed to recover the alcohol. These alcohols which are predominately secondary are used in surfactant manufacture.

Synthesis from Alkylaluminums. Fundamental work on organoaluminum chemistry by Prof. Karl Ziegler and co-workers at the Max Planck Institute provided the basis for a commercial synthesis of even-carbon-numbered straight chain primary alcohols. These alcohols are identical with products derived from naturally occurring fats. In this process, ethylene is reacted with aluminum triethyl to form a higher alkylaluminum which then is oxidized and hydrolyzed to give the corresponding alcohols.

(14) $(C_2H_5)_3Al \xrightarrow{CH^2=CH^2}$

$$[CH_3(CH_2CH_2)_nCH_2]_3\ Al \xrightarrow[(2)\ H_2O]{(1)\ O_2} 3\ CH_3\ (CH_2CH_2)_n\ CH_2OH + Al(OH)_3$$

Commercialization of this route to higher alcohols is the most significant development in this area in recent years.

Synthesis from Natural Products. Many alcohols are prepared by reduction of the corresponding methyl esters which are derived from animal or vegetable fats. These alcohols are straight chain even-carbon-numbered compounds. Tallow and coconut oil are two major raw materials for higher alcohol manufacture.

(15) $(RCOO)_3C_3H_5 + 3\ CH_3OH \longrightarrow 3\ RCOOCH_3 + \underset{\textit{Triglyceride}}{CH_2OHCHOHCH_2OH}$

(16) $RCOOCH_3 + 2\ H_2 \xrightarrow{\text{Catalyst}} RCH_2OH + CH_3OH$

The production of ethyl alcohol for beverage, cosmetic, and pharmaceutical products is commonly accomplished by the natural process of fermentation. See **Ethyl Alcohol**; **Methyl Alcohol**; and **Fermentation**. Beer, wine, and whiskey production are extensively covered in the *Foods and Food Production Encyclopedia* (D.M. and G.D. Considine, Eds.), Van Nostrand Reinhold, New York, 1982.

ALCOHOLS, POLYHYDRIC. See **Polyhydric Alcohols**.

ALCOHOLYSIS. If a triglyceride oil is heated with a polyol, such as glycerol or pentaerythritol, mixed partial esters are produced in a reaction known as *alcoholysis*.

ALCYONARIA. An order of the class *Anthozoa* (*Actinozoa*) in the phylum *Coelenterata*. The animals of this order are marine and because of the hard deposits formed in and around their bodies they are often known as corals. Among them are the sea-pen, the sea-fan, organ-pipe coral, and precious coral.

Alcyonaria are usually found in colonies. The individuals are polyps connected together by living structures and by the hard skeletal structures.

They differ from the true corals in having only eight tentacles, pinnately branched. See also **Coelenterata**.

ALDEBARAN *(α Tauri).* A star whose name is derived from an Arabic phrase indicating that the star is the "leader of the followers," i.e., the leader of the asterism known as the Hyades, which follow the Pleiades in their nightly journey across the sky. Astrologically, Aldebaran was a fortunate star, portending riches and honor. This star was one of the four royal stars of the Persians about 3000 B.C.

Aldebaran is one of the smaller stars, whose diameter has been measured with the stellar interferometer. The diameter is found to be about 6.4×10^7 kilometers, or 46 times the diameter of our sun. Ranking fourteenth in apparent brightness among the stars. Aldebaran has a true brightness value of 100 as compared with unity for the sun. Estimated distance from the earth is 53 light years. Aldebaran is classified as a star of orange color and of spectral type K. See also **Constellations**; and **Star**.

ALDEHYDES. The homologous series of aldehydes (like ketones) has the formula $C_nH_{2_n}O$. The removal of two hydrogen atoms from an alcohol yields an aldehyde. Thus, two hydrogens taken away from ethyl alcohol $CH_3{\cdot}C(H_2)OH$ yields acetaldehyde CH_3CH_2OH; and two hydrogens removed from propyl alcohol $C_2H_5{\cdot}C(H_2)OH$ yields propaldehyde $C_2H_5{\cdot}CHO$. The trivial names of aldehydes derive from the fatty acid which an aldehyde will yield upon oxidation. Thus, formaldehyde is named from formic acid, the latter being the oxidation product of formaldehyde. Similarly, acetaldehyde is oxidized to acetic acid. Or, the aldehyde may be named after the alcohol from which it may be derived. Thus, formaldehyde, which may be derived from methyl alcohol, may be named methaldehyde; or acetaldehyde may be named ethaldehyde since it may be derived from ethyl alcohol. In still another system, the aldehyde may take its name from the parent hydrocarbon from which it theoretically may be derived. Thus, propa*nal* (not to be confused with propa*nol*) may signify propaldehyde (as a derivative of propane).

Essentially aldehydes exhibit the following properties: (1) with exception of the gaseous formaldehyde, all aldehydes up to C_{11} are neutral, mobile, volatile liquids. Aldehydes above C_{11} are solids under usual ambient conditions; (2) formaldehyde and the liquid aldehydes have an unpleasant, pungent, irritating odor, (3) although the low-carbon aldehydes are soluble in H_2O, the solubility decreases with formula weight, and (4) the high-carbon aldehydes are essentially insoluble in H_2O, but are soluble in alcohol or ether.

The presence of the double bond (carbonyl group C:O) markedly determines the chemical behavior of the aldehydes. The hydrogen atom connected directly to the carbonyl group is not easily displaced. The chemical properties of the aldehydes may be summarized by: (1) they react with alcohols, with elimination of H_2O, to form *acetals*; (2) they combine readily with HCN to form *cyanohydrins*, (3) they react with hydroxylamine to yield *aldoximes*; (4) they react with hydrazine to form *hydrazones*; (5) they can be oxidized into *fatty acids*, which contain the same number of carbons as in the initial aldehyde; (5) they can be reduced readily to form primary alcohols. When benzaldehyde is reduced with sodium amalgam and H_2O, benzyl alcohol $C_6H_5{\cdot}CH_2{\cdot}OH$ is obtained. The latter compound also may be obtained by treating benzaldehyde with a solution of cold KOH in which benzyl alcohol and potassium benzoate are produced. The latter reaction is known as Cannizzaro's reaction.

In the industrial production of higher alcohols (above butyls), aldehydes play the role of an intermediate in a complete process that involves aldol condensation and hydrogenation. In the OXO process, olefins are catalytically converted into aldehydes that contain one more carbon than the olefin in the feedstock. Aldehydes also serve as starting materials in the synthesis of several amino acids. See also **Acetaldehyde**; **Aldol Condensation**; **Benzaldehyde**; and **Furfuraldehyde**.

ALDERFLY *(Insecta, Neuroptera).* The alderflies belong to the order *Neuroptera*, suborder *Megaloptera*. These are the most primitive members of the order, and the most primitive of all holometabolous insects. There are only two members of the *Megaloptera* in Europe, both of which are Alderflies (family *Sialidae*). These are small, with a wingspan of only 3 centimeters (1 inch). *Sialis lutaria* is commonly found in central Europe in the spring or summer, sitting on shore plants by still or slowly flowing waters. The second species, *Sialis fuliginosa*, is usually rather more dusky in color and differs from the first in the wing venation and the structure of the hind end of the body. The Smoky Alderfly (*Sialis infumata*) of the United States, with brownish-black wings, is similar in size and habits to the European species. At rest, the alderflies lay their wings together over the body like a roof, as do almost all the *Neuroptera*. They are hunters, both as adults and as larvae. The larvae, however, are aquatic.

ALDER, KURT (1902–1958). Kurt Alder was a German organic chemist, and one of the discoverers of the Diels–Alder reaction. The son of a teacher, Alder was born in Königshütte, Germany, now Chorzów in Poland. In 1922 he entered the University of Berlin but later transferred to the University of Kiel, where he studied chemistry under the direction of Otto Diels and received his PhD in 1926. In 1930 he was appointed Reader in Organic Chemistry at Kiel, becoming Professor in 1934. During this period he began the research with which he is most closely associated. Working with Diels, he developed a synthetic method which involves the addition of dienes (unsaturated compounds with alternating double bonds) to dienophiles (compounds having a double bond activated by a nearby carbonyl or carboxyl group), the product usually being a six-membered ring. In 1950 Alder and Diels shared the Nobel Prize in chemistry for their discovery and development of the diene synthesis (the Diels–Alder reaction).

First reported in 1928, this method proved to be both versatile and gentle. It was found to have a role in biosynthetic reactions in nature, and is used as one of the steps in the artificial production of some vitamins and hormones. It is also used during the commercial preparation of dyes, drugs, insecticides, lubricating oils and synthetic polymers.

ALDER TREES. Members of the family *Betulaceae* (birch family), these trees are of the genus *Alnus*. They are deciduous trees or shrubs and are considered very hardy.

The red alder is found in forests on the west coast of the United States and Canada, from California northward to Alaska. The average height is from 40 to 60 feet (12 to 18 meters). However, as will be noted from the accompanying table of record alder trees, the red alder can reach heights of close to 100 feet (30 meters). The white alder occurs on the Pacific slopes and can attain a height of over 100 feet (30 meters), although the average is from 50 to 70 feet (15 to 21 meters). Staminate flowers are contained in catkins of about 5 inches (13 centimeters) in length. The cones range from $\frac{1}{2}$ or $\frac{7}{8}$ inch (1.2 to 2.2 centimeters) in length. The leaves are ovate and of a light yellow-green color. The tree ranges from northern Idaho westward to southeastern Oregon, with preference for the eastern slopes of the Cascade Mountains. The tree also is found in the Coastal Range and Sierra Nevadas down into southern California.

Alder wood is durable and well suited for applications in wet and damp areas, as may be required for sashes and bridge construction. In areas where forest fires have cleared the land, alders are fast-growing and come up abundantly. Alders have nodules which form on the root and which help to enrich the soil. However, if hemlock and Douglas fir are present, these latter trees can soon overtake the alder in height, smothering out all except the very strongest trees. Alder lumber is usually shipped from west coast forests. In the green condition, red alder has a moisture content of 98% and weighs 46 pounds per cubic foot (737 kilograms per cubic meter). When air-dried to 12% moisture content, the weight is 28 pounds per cubic foot (448.5 kilograms per cubic meter), with 1,000 board-feet (2.36 cubic meters) of nominal sizes weighing about 2330 pounds (1057 kilograms). Crushing strength when compression is applied parallel to the grain is 2960 psi (20.4 MPa) for the green wood; 5820 psi (40.1 MPa) for the dry wood. Tensile strength when tension is applied perpendicular to the

TABLE 1. RECORD ALDER TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Arizona alder (1982) (*Alnus oblongifolia*)	199	505	129	39.3	50	15.2	New Mexico
European alder (1982) (*A. glutinosa*)	131	333	70	21.3	40	12.2	Illinois

[1]From the "National Register of Big Trees," American Forests' (by permission).
[2]At 4.5 feet (1.4 meters).

green wood is 390 psi (2.7 MPa) for the green wood, 420 psi (2.9 MPa) for the air-dried wood.

Record alder trees in the United States are listed in Table 1.

ALDOL CONDENSATION. A reaction between aldehydes or aldehydes and ketones that occurs without the elimination of any secondary product and yields β-hydroxycarbonyl compounds. It is distinguished from polymerization by the fact that it occurs between aldehydes and ketones and is not generally reversible. In its simplest form it may be represented by the condensation of two molecules of acetaldehyde to aldol:

$$CH_3{\cdot}CHO + CH_3{\cdot}CHO \longrightarrow CH_3{\cdot}CHOHCH_2{\cdot}CHO$$

Weak alkalies and acids are employed to effect the condensation.

Researchers at the University of California, Berkeley, have accomplished acyclic stereocontrol through the aldol condensation. As observed by C.H. Heathcock (*Science*, **214**, 295–400, Oct. 23, 1981), one of the most difficult problems in the synthesis of complex organic compounds is that of controlling the relative stereochemistry, that is, establishing the correct configuration at the various chiral centers as the synthesis is carried out. In recent years, researchers have been attempting to find direct solutions to the problem, particularly in synthesizing acyclic and other conformation- flexible molecules. Heathcock and colleagues have found that aldol condensation, one of the oldest and most familiar organic reactions, can be a very effective tool for achieving stereocontrol.

ALDOSES. See **Carbohydrates.**

ALDOSTERONE. See **Steroids**.

ALDOXIMES. See **Hydroxylamine**.

ALEURONE GRAINS. Protein reserves found in the seeds of several different kinds of plants. In many plants there is a special aleurone layer of definite thickness found in the endosperm. In corn (maize), the layer is a single cell in thickness and may contain a colored pigment; in oats, it is two cells thick. In the castor oil plant, the aleurone grains are not restricted to a single layer, but are distributed rather generally in the endosperm, and have a complex structure.

ALEUTIAN CURRENT. See **Ocean Currents**.

ALEUTIAN LOW. See **Meteorology**.

ALEWIFE *(Osteichthyes)*. A common fish (*Pomolobus pseudoharengus*) of the Atlantic coast. It is related to the herring and shad. It enters the streams to spawn and is found in lakes of New York. The alewife is generally considered an unsatisfactory food fish. Normally found in marine waters, Nova Scotia to Florida. Maximum length about 11 inches (28 centimeters).

ALEXANDRITE. A variety of chrysoberyl, originally found in the schists of the Ural Mountains. It absorbs yellow and blue light rays to such an extent that it appears emerald green by daylight but columbine-red by artificial light. It is used as a gem, and was named in honor of Czar Alexander II of Russia. See also **Chrysoberyl**.

ALFALFA. Of the family *Leguminosae* (pea family), alfalfa (*Medicago sativa*), is a plant native to southwestern Asia. It is an important perennial forage plant, extensively cultivated since the Roman civilization. The plant has a very deeply penetrating root system, reaching down 25 feet (7.5 meters) or more and thus is well suited for growing in dry lands where resistance to drought is important. The fragrant, purplish flowers are a good source of honey. The plants are cultivated principally for hay. See also **Leguminosae**.

ALFVÉN WAVE. A transverse wave in a hydromagnetic field in which the driving force is the tension introduced by the magnetic field along the lines of force. The dynamics of such waves are analogous to those in a vibrating string, the phase speed being given by

$$C^2 = \mu H^2/4\pi\rho \tag{1}$$

where μ is the permeability, H the magnitude of the magnetic field, and ρ the fluid density. Dissipative effects due to fluid viscosity and electrical resistance may also be present.

For proton-electron plasmas, a simpler expression than that of Equation (1) may be obtained in terms of the magnetic field strength, B, and the number of charged particles, n, per unit volume. This expression gives the phase velocity as

$$C = \frac{(1.7 \times 10^6)B}{n^{1/2}}$$

The Alfvén wave behaves like a conventional shock wave, such as a supersonic sound wave, in having a high energy front resulting from an excess of the plasma velocity over the Alfvén velocity. However, it differs in that it is produced by the interaction of waves instead of particles, since the latter, in, for example, a plasma in the upper atmosphere or in space, are too widely spaced to have an appreciable number of collisions.

ALFVÉN, HANNES OLOF GÖSTA (1908–1995). Alfvén was born in Norrköping, Sweden and made important contributions to the development of modern physics. Two experiences may have led him towards his career. One experience was a childhood gift of an astronomy book, and the other experience was working with his school's radio club.

Alfvén was awarded a Ph.D. from the University of Uppsala in 1934. He worked as a research physicist at the Nobel Institute of Physics first, then moved to the Royal Institute of Technology. Alfvén had the ability to take simple observations and deduce larger principles. His early theoretical research involved the fourth state of matter, plasma, and the behavior of plasmas in electrical and magnetic fields. Alfvén showed that hydromagnetic waves (Alfvén waves) could exist in plasmas such as the ionized gas emitted by the Sun.

Alfvén objected to Sweden's nuclear program and in 1967 left and went to Russia for several years. Later, he came to the United States and accepted a position at the University of California, San Diego.

Important advances in space physics have been made because of Alfvén's work. He received the Nobel Prize for physics with Louis Neel in 1970 for work and discoveries in magnetohydrodynamics with applications in plasma physics.

See also **Alfvén Wave**; **Hydromagnetic Equations**; and **Plasma (Particle)**.

JEANNE MAREE IACONO, Dammeron Valley, UT

ALGAE. Thallophytes characterized by possessing chlorophyll, and so capable of elaborating their food by photosynthesis. Often the green pigment is completely concealed by other pigments, so that the plant is brown, red, or even black.

Algae are found in almost every habitat. In the oceans vast numbers of minute species float suspended in the upper levels of the water, while

the shores are covered with many and varied forms from high tide level to depths of 30 feet (9 meters) or more. In fresh water they are equally abundant, but due to their smaller size are seldom so conspicuous as the marine forms; they occur in running water, in ponds, and in stagnant, often putrid, water. Many species are found only in hot springs. They are found on the surface of the ground, on the bark of trees, on rocks, and even underground to a depth of several feet. A few species have found a favorable habitat within the bodies of higher plants and animals. In fact, wherever they find support and can obtain the necessary materials for growth, there algae may be found.

Algal plants offer a wonderful diversity of forms. In size they range from unicellular microscopic plants to structures having dimensions comparable to the larger land plants. The plankton forms, those free-floating plants often so abundant in both fresh and salt water, are nearly all unicellular; other free-floating forms, usually found near shore or in small fresh water ponds and streams, are multicellular organisms of various shapes, filamentous forms being especially common. Finally, attached marine forms often attain massive dimensions. The common kelp, or devil's apron, of the colder coastal waters of North America, may grow to a length of 30 feet (9 meters) or more, and to a width of 2 or 3 feet (0.6 or 0.9 meters), while related species found in the Pacific Ocean far exceed them in size, reaching lengths of 100 feet (30 meters) and more.

Not only do algae vary greatly in size, but they also show almost every conceivable shape. Unicellular types are often adorned with a complex but beautifully symmetrical series of arms, or bristles, which may be of service in keeping them floating in the water. The filamentous forms may be simple or very much branched; often they are delicate plants of rare beauty. Other algae grow in flat sheets or membranes, either spreading over the substratum or rising gracefully in the water. The larger forms are of coarser habit, varying from irregular tumorous plants to long slender cords and broad flat fronds. Plants of the genus *Sargassum*, one of the brown algae found in warm regions, have an appearance very similar to that of flowering plants. Each plant has a slender branching stalk, often 2 feet (0.6 meters) or more in length. From this stalk flat lateral branches arise, which look very much like leaves, except for their brown color. Other short lateral branches end in small sub-spherical balls easily mistaken for fruits. Actually these structures are hollow bladders which help to keep the plant floating. Other branches, the real reproductive parts of the plant, are short cylindrical objects that might be mistaken for buds. At first the plant grows on rocks and other solid objects. It is easily broken loose, however, and floats about in the ocean currents. Thus, these plants are frequently washed up on northern beaches.

There are several systems of classification of algae, varying in details but all using the various pigments found in their cells as a basis for separation. Obviously, such a classification is very artificial, but in the algae it seems to agree quite closely with natural systems based on such other criteria as the structure of the thallus or plant body, the substances formed by the cells and stored in them, and especially the reproductive processes which are found in the different groups.

The algae are now commonly separated into seven divisions or phyla, although in an older system these groups had the status of Class. The four larger phyla are the *Cyanophyta* or blue-green algae. *Chlorophyta* or green algae, *Phaeophyta* or brown algae, and the *Rhodophyta* or red algae. The smaller phyla are the Euglenophyta or Flagellates, the Chrysophyta, including the yellow-green and golden-brown algae and the diatoms, and the Pyrrophyta or cryptomonads.

The blue-green algae are characterized by having within the cell, in addition to chlorophyll, a bluish pigment, phycocyanin. These pigments are not localized in a definite pigment-bearing body or plastid, but are frequently diffused in the outer zone of protoplasm. Surrounding the protoplasm is a definite cell wall of cellulose (see **Carbohydrates**). In most blue-green algae the outer part of the wall is modified and becomes a soft slimy substance that often forms a layer of considerable thickness. This slime substance may be of great value as insulation against heat and desiccation, thus enabling blue-green algae to live in what seem to be most unfavorable environments. In the central portion of the protoplast are found many chromatin bodies, which, however, are not organized into a definite nucleus. The structure of the cell of these algae, with its absence of plastids and any definite nucleus, seems to indicate a relatively primitive organism, and is suggestive of the structure found in bacteria. See Fig. 1.

Many blue-green algae are single-celled organisms. The individual cells are often separate or they may be held together by the gelatinous outer wall

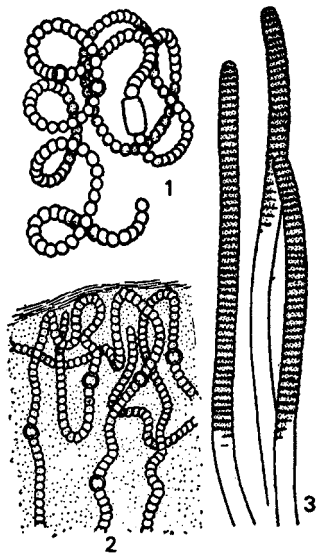

Fig. 1. Three species of *Myxophyceae*: (1) filaments of a species of *Anabaena*; (2) filaments of *nostoc* encased in the characteristic jelly; (3) *Oscillatoria*. (*After Smith and Fremy*.)

in aggregates sometimes of considerable size. Representatives of this group are frequently observed in temporary puddles formed by a summer shower or in quiet shallow ponds in which the water often becomes very warm. Some of them are of considerable economic importance, when they appear in water supply reservoirs. In these they sometimes occur in numbers so great as to color the water and to be only too obvious to the most casual observer. Such occurrences are frequently described as "water-blooms." Due to the products formed by the metabolism of the cells and liberated into the water, such "blooms" are real problems because not only do these substances give the water a distinctly unpleasant, oily fishy taste and color, but several cases are recorded in which drinking of such water has been quickly fatal to livestock.

Other blue-green algae occur as simple filaments of cells. Single filaments may occur among other algae or they may exist in extensive masses covering considerable areas with a soft felt-like layer. In some genera many filaments are held together in a common gelatinous sheath. Many blue-green genera show what is called false branching. The rapid division of cells in the middle of a filament causes them to grow out laterally. Sometimes the filaments grow out as a single branch, as in *Tolypothrix*, or in pairs, as in *Scytonema*. True branching is found in a few genera.

In all the non-filamentous species the only method of reproduction is that of cell division. In the filamentous forms continued division may produce a filament of indefinite length. However, it eventually breaks up. This fragmentation may be due to animals feeding on cells of the filament, or to the death of certain cells. In some forms it is due to the development of cells which do not adhere tenaciously to the cells adjoining them. Specialized cells known as heterocysts are largely responsible for the last condition. They are large transparent cells that develop from ordinary cells. See Fig. 2.

Blue-green algae, particularly abundant in regions having a warm climate, develop elsewhere in great abundance, during the warmer seasons of the year. Besides being a source of trouble in water reservoirs, blue-green algae sometimes form unsightly stains by growing on the walls of stone buildings, especially if the latter be constantly wet. Some of the blue-green algae have the ability to fix nitrogen (see **Bacteria**). It has been suggested that this may be important to such crops as rice.

The green algae, or Chlorophyta, are found in both salt and fresh water, where they often form conspicuous masses. They are characterized by a bright green color. The reserve food stored by these algae is starch, which is usually found around certain bodies known as pyrenoids, located in the chloroplasts.

The green algae are of considerable interest because of the possibility that from them the higher plants may have arisen, and because of the diversity of forms which are found within in the group.

The protoplasts of the green algae are with very few exceptions enclosed within a rigid wall composed of two layers, an inner made up wholly or

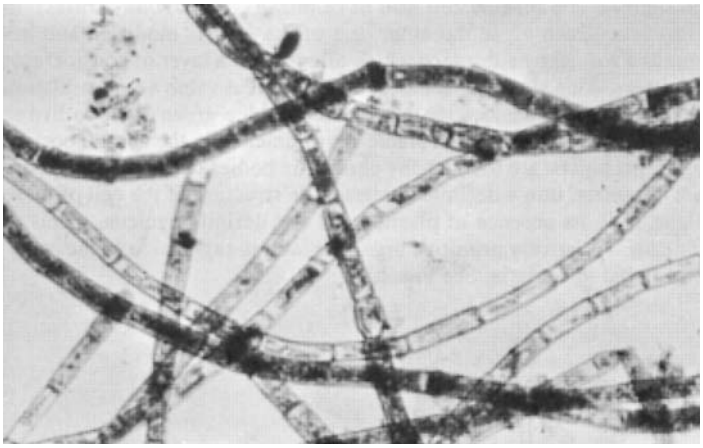

Fig. 2. *Oedogonium*. Filamentous cells in fresh water. (*Photomicrograph by B.J. Ford; copyright*.)

largely of cellulose and an outer layer of pectin (see **Carbohydrates**). Within the protoplast of the cell is located one or more conspicuous chloroplasts containing pigments approximately like those occurring in the plastids of higher plants. The chloroplasts of any single genus are usually very constant in appearance but in the different genera remarkable diversity of size and shape exists. The primitive form seems to be the massive cup-shaped type such as occurs in many lower Chlorophyta. The nucleus of all green algae is a definitely organized body possessing a nuclear membrane, one or more nucleoli, nuclear sap (karolymph), and chromosomes. Many unicellular forms have one or more cilia that persist throughout their existence. The reproductive cells of most green algae have cilia. See **Cilium**.

Reproduction in green algae takes place in various ways. One is a strictly vegetative process in which the colony, or filament, of cells is broken up by various external agents, after which each fragment becomes a new colony, or filament.

Asexual reproduction is by means of cell division (nuclear division followed by division of the cytoplasm) or by zoöspore formation. These zoöspores are generally formed from the protoplast of any vegetative cell, and may appear singly or in numbers by division of a single protoplast. They are expelled from the cell in a manner as yet unknown and are frequently enclosed in delicate vesicle at the time of expulsion. The zoöspores are naked bodies, having no cell wall, and possessing apical cilia. *Vaucheria* is an exception, for its zoöspores are covered with cilia. After periods of motility varying from a few minutes to many hours, zoöspores become quiescent, withdraw their cilia, secrete a cell wall and develop to new colonies or organisms like the parent form.

Finally, many green algae possess a sexual reproduction, which is often very complicated. In sexual reproduction there are formed two sets of reproductive bodies known as gametes, which fuse in pairs to form a zygote. From the zygote a new plant develops.

The great diversity of form found in the green algae makes them interesting plants to examine for lines of evolution which have produced the many forms existent today. Several different lines have been found. One of these includes many of the forms that remain motile throughout their existence. A relatively simple unicellular organism is the starting point for such a line. *Chlamydomonas* is of this type. The plant is a small spherical or oval cell enclosed in a definite cell wall and having two apical cilia. Within the protoplast there is a single massive chloroplast which has a shape like that of a soft rubber ball pushed deeply in on one side. Within the hollow of the plastid the single distinct nucleus is located. At the apex of the cell near the origin of the two cilia there is a minute red body called an eye-spot. This is a light-sensitive organ which when stimulated causes the organism to move toward or away from the light source. In the apical end there is a pair of contractile vacuoles. *Chlamydomonas* reproduces asexually by means of zoöspores. These are formed by divisions of the protoplast to form 2, 4, or 8 daughter protoplasts, contained within the wall of the original cell. This wall softens and liberates these naked cells. At once they become small replicas of the parent cell. They soon grow to the size of the original cell and again form a new group of zoöspores. In a suitable environment this is a very rapid method of reproduction. *Chlamydomonas* also reproduces sexually.

In sexual reproduction the protoplast of the cell divides to form motile bodies called gametes, which are quite like zoöspores, but smaller. On liberation from the parent cell wall, gametes from different cells unite in pairs, and form zygotes, which develop into zygospores. A zygospore is a resistant spore with a thick wall that enables the organism to survive periods of adverse conditions. When favorable conditions return, the contents of the zygospore divide to form zoöspores, which behave as do similar spores from motile cells.

The primitive character of *Chlamydomonas* is found in its contractile vacuoles, its eye-spot, its single massive plastid, and its cilia. From Flagellates it differs only in having a definite cell wall. Comparing other motile green algae with *Chlamydomonas* makes it possible to discover an interesting series of species of increasing complexity. First in this series is *Gonium sociale*, with colonies of four cells, and *Gonium pectorale*, with sixteen cells, held together loosely in a gelatinous matrix. All the cells of a colony are alike and any cell may form either zoöspores or gametes. All gametes are alike, but fusion occurs between gametes from different colonies. Next in the line of increasing complexity is *Pandorina*, in which a spherical colony is formed. In this genus the gametes are slightly different in size and behavior, some being small and active, while others, slightly larger, are more sluggish. This is an indication of a differentiation of sex.

Still further advance is shown by *Eudorina*, in which a colony is composed usually of 32 cells located in the peripheral portion of the gelatinous matrix. Each cell of the colony is like a *Chlamydomonas* cell and each is capable of reproducing asexually. But in sexual reproduction a very obvious difference in sexes is apparent. Some colonies are definitely female, the cells enlarging slightly and functioning as eggs. In other colonies, each cell divides to form 64 minute biciliate sperm. Fusion between an egg and a sperm produces an oöspore, which gives rise to a new colony. In *Pandorina*, then, a very obvious distinction between sexes has appeared, but the vegetative cells remain alike. In *Pleodorina* each colony is composed of small, purely vegetative cells and larger reproductive cells. The smaller vegetative cells are formed in the anterior end of the colony. In *Volvox* we find the highest degree of differentiation exhibited in this line of motile algae. In this plant the number of cells in a colony is very great, in some species there being as many as 25,000. Of these cells only a few are reproductive, while thousands remain vegetative. Many *Volvox* colonies are so large as to be readily visible to the unaided human eye. In these the many cells form a single layer embedded in the gelatinous matrix. The center of the colony is either water or a thin gelatinous substance. The cells of the colony have the same structure as *Chlamydomonas* cells. They are joined together by fine protoplasmic strands. The beating of the cilia causes the large colony to roll rapidly about in the water, making it a fascinating object to watch. In asexual reproduction certain cells of the colony enlarge and move to the central region. There they lose their cilia, after which they divide rapidly to form new colonies which remain for some time within the parent. Often a single colony will contain a dozen or more of these small colonies. The latter are liberated by the disintegration of the parent colony. In sexual reproduction, cells in the posterior region of the colony differentiate. Some lose their cilia and become very large; these are eggs. Other cells, either in the same or different colonies, divide many times to form large numbers of minute biciliate sperm. These swim to the eggs. A single sperm enters an egg, its nucleus fusing with that of the egg. As a result a zygote is formed. This secretes around itself a thick wall and becomes an oöspore, capable of enduring protracted periods of unfavorable conditions. With the return of favorable conditions the thick wall of the oöspore breaks, the protoplast emerges and divides rapidly, forming a new colony. *Volvox* represents the climax reached in this line of evolution. There is not only a very great increase in the number of cells forming a colony, but also a distinct separation of vegetative and reproductive cells. The reproductive cells are of two kinds, eggs and sperm. But every cell of the plant retains the primitive character of the individual cell.

It is possible to build up other evolutionary series of green algae in which the vegetative cells are non-motile. *Chlamydomonas* often assumes a non-motile condition; the cells become embedded in a copious gelatinous matrix and lose their cilia. This condition is known as the palmella stage. *Tetraspora* is an alga that has the appearance of the palmelloid stage of *Chlamydomonas*. See Fig. 3. Another genus, *Palmella*, normally exists as a shapeless colony of cells held together in a gelatinous matrix. Cilia are lacking, but may be developed by any cell in the colony. A ciliated cell escapes and swims about freely for a time, then settles down and divides to form a new colony. Asexual zoöspores are formed in *Palmella*

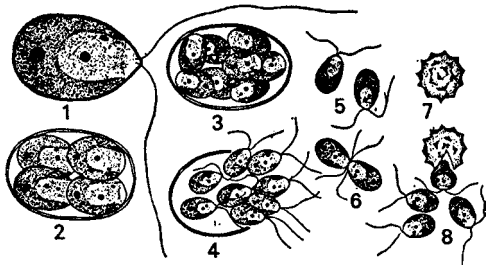

Fig. 3. *Chlamydomonas*: (1) mature cell; (2) four young cells formed in asexual reproduction; (3) eight gametes formed by the division of one cell; (4) gametes escaping from old cell wall; (5) free-swimming gametes; (6) two gametes conjugating; (7) resting zygote; (8) four cells formed from the zygote.

and also isogametes, that is, gametes of equal size. *Palmella* shows the beginning of a non-motile habit, with a restriction of the motile stages to the reproductive cells. In *Geminella* the amorphous habit of the colony is lost; divisions take place in such a way that the resulting cells tend to exist in a single series, the individual cells being held together only by the gelatinous matrix around them. In *Ulothrix* further advance is made. See Fig. 4. In this plant the protoplast of the cell divides within the wall of the cell. But it does not escape therefrom; instead cross-walls are formed between daughter protoplasts which remain permanently joined. Repeated divisions in a single direction result in the formation of a long unbranched filament of cells. Asexual reproduction in *Ulothrix* is by zoöspores. These are very similar to the cells of *Chlamydomonas*, but each has 4 cilia. From each zoöspore new filaments are formed directly. Sexual reproduction is by biciliate gametes, which are formed in the usual manner. Two gametes fuse to form a zygote, which develops a thick wall, becoming a zygospore, and on germinating produces zoöspores. In some species of *Ulothrix* the gametes are alike, while in others slight differences in size of the gametes produced from different cells indicate the beginning of sex differentiation.

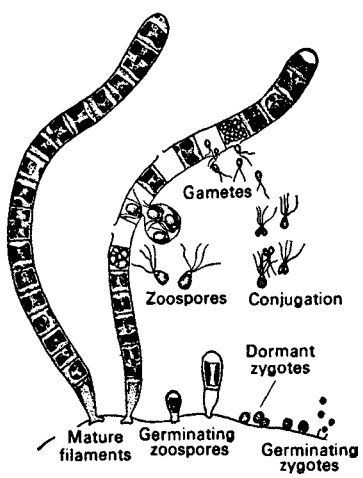

Fig. 4. *Ulothrix*. Stages in development.

Other genera of algae, related to *Ulothrix*, show greater differentiation in the vegetative cells. Branching occurs in many; certain cells produce the zoöspores or gametes. Other genera, notably the marine *Ulva*, the Sea Lettuce, have cell divisions in two planes, so that extensive membranes are formed, often two meters or more in length.

The highest stage of development in this series is found in *Coleochaete*. This alga appears as small disks epiphytic on other aquatic plants. It consists of branching filaments, which in some species grow out to form a flat shield-like thallus. Asexual reproduction is by biciliate zoöspores, which are formed singly from the protoplast of any cell. In its sexual reproduction, *Coleochaete* is especially interesting, exhibiting an advanced degree of differentiation of sex cells called oögamy. The eggs are formed in special cells at the tips of certain filaments. By continued growth, the vegetative cells form a layer enclosing the oögonium. From the oögonium a projection called the trichogyne grows out; in some species it remains short, but in one at least it becomes long and slender. The biciliate sperm are formed singly in special cells known as antheridia. A single sperm enters the egg through the trichogyne or papilla, through a soft place that forms in the wall. Following fertilization, or the union of egg and sperm, the fertilized egg enlarges greatly and secretes around itself a thick wall, in which condition it remains very resistant to external changes. On germination its contents divide to produce 16 or 32 cells, each of which produces a zoöspore. These give rise to new plants. In *Coleochaete* we have a highly developed end product to an advancing degree of differentiation of cells and development of sex.

Many other equally interesting lines of evolution can be found in green algae. One leads to *Vaucheria*, a branching filamentous plant in which cross walls are not formed, nuclear divisions occurring until an extensive multinucleate filament is formed. Many marine relatives of *Vaucheria*, especially abundant in tropical seas, have elaborate bodies, often thickly encrusted with lime. In the genus *Caulerpa* the thallus of some species appears to be differentiated into leaves, stems and roots; however, no differentiation of tissue occurs, the whole structure being essentially filamentous.

Another group of algae, found only in fresh water, is the Conjugales. This includes the frequently observed *Spirogyra*, a genus having spiral chloroplasts. See Fig. 5. Sexual reproduction in *Spirogyra*, as in all the Conjugales, is by a process called conjugation. When the cells of two filaments are to conjugate they come into contact one with another. From the cells of one filament projections grow outward to meet similar projections from the cells of the other filament. These projections meet, and the walls at their tips are absorbed, leaving a tube connecting two cells of opposite filaments. Through this tube the protoplast of one cell moves into the opposite cell, where fusion occurs. Following this the zygote thus formed surrounds itself with a thick wall. This zygospore is extremely resistant to unfavorable external conditions, such as drought. After a prolonged rest period, if environmental conditions are favorable, the wall of the zygospore breaks, and a tube grows out from the protoplast within. By divisions, this tube becomes a new filament. Observation of conjugating filaments of *Spirogyra* reveals two facts: first, that when one cell of a filament conjugates with a cell of another filament, commonly all the cells of the first filament are conjugating with those of the other; second, that movement is largely from one filament to the other, so that at the end of the process one filament is composed of empty cell walls and the other filled with zygospores. This may be conceived as a sexual condition, the empty cells having been male and the cells in which the zygospores formed, female. Many related algae in the Conjugales show no indication of sexuality, the protoplasts uniting in the tube joining the two cells. No ciliated cells of any sort occur in this order.

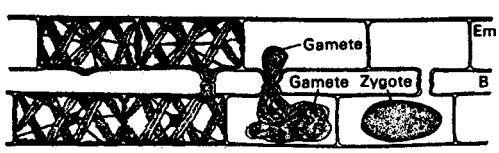

Fig. 5. *Spirogyra*. Stages in conjugation.

Related to *Spirogyra* is a family containing many species whose cells are very symmetrical and beautiful objects. This is the Desmidiaceae, a family whose members commonly occur as single cells composed of two symmetrical halves. In many species the halves are distinctly indicated by a deep constriction which leaves only a slender isthmus connecting them. Conjugation in the Desmids is essentially like that in the other Conjugales.

Except for their botanical interest and for the fact that they provide food for many animals, the green algae are of little significance to man. Recently, however, investigations have been conducted to determine the feasibility of raising green algae as human food. One of the most promising of these algae is Chlorella, and some of its possibilities in food production are described under **Chlorella**.

The brown algae, or Phaeophyta, are distinguished from other algae by the presence of the brown pigment fucoxanthin, which masks the chlorophyll present and which imparts to them a brown color. Nearly all are marine plants. In this group there are no very simple primitive forms, comparable to *Chlamydomonas* of the greens. The simplest forms, such as *Ectocarpus*, are branched filamentous plants.

Other brown algae are very large, with tough bodies of many, often complex shapes. They are most numerous on rocky coasts, where they grow

attached to the rocks and are often exposed to the severest pounding of the tides. Brown algae are found in all regions, but are especially abundant in the cold temperature and arctic waters. One genus, *Sargassum*, occurs in great abundance floating in the Atlantic Ocean, forming the Sargasso Sea, through which Columbus passed so slowly on his voyage of discovery. Probably these plants are carried by ocean currents from the shores where they grow to the Sargasso Sea, where they float endlessly. The brown algae include the largest plants of this division of the plant kingdom, many of the kelps growing 30–40 feet (9 to 12 meters) long, and some of the plant forms of the Pacific Ocean attaining lengths of a hundred feet and more.

All brown algae are multicellular plants. Each cell contains a single distinct nucleus and several chloroplasts which contain chlorophyll, carotene, xanthophyll and fucoxanthin. The presence of the latter hides the other pigments. Photosynthesis in brown algae, as in other plants, results in the formation of sugar. This sugar however is changed into a compound, laminarin, instead of starch, which is never found in this group of algae.

The Phaeophyta are divided into several groups. These show interesting differences in their life histories. In most of them there is a very definite alternation of generations. Plants of the sexual generation form gametes; the asexual generation forms zoöspores. The motile cells of the brown algae are quite distinct from those of the green algae, having 2 unequal cilia which are attached laterally and extend in opposite directions.

One of the orders of this class is the Ectocarpales, of which *Ectocarpus* is a common form. See Fig. 6. It occurs as soft brown tufts growing on other larger algae or on stones or woodwork in the water. Each plant is composed of slender branching filaments. In this genus there is a definite alternation of two generations that are indistinguishable in the vegetative condition. Plants of the sexual generation are haploid, that is, have the reduced number of chromosomes and bear gametangia. These are elongated structures composed of many small, cubical cells. Each of these cells forms a single gamete. The plants of this generation and the gametangia they bear all look exactly alike. The gametes they produce also look very much alike. But in behaviour they are different. Some are sluggish, moving but little, while others swim actively and are attracted to the sluggish ones from other plants. The active gametes are males, the others females; sometimes the female gametes are slightly larger than the males. One male gamete fuses with a female, forming a zygote. The zygote always forms an asexual plant, which is diploid. There are two kinds of asexual plants, which look exactly alike, and also like a sexual plant. Each forms zoösporangia. One form of zoöspórangium, called a plurilocular zoösporangium, is composed of many small cubical cells, each of which forms a single zoöspore. These zoöspores are liberated, swim about for a time, sink to the bottom and settle against any solid substratum and give rise to new asexual plants of the same type as that producing them. The other type of zoösporangium, often found on the same plant as the first, is composed of a single, usually much-enlarged, cell. The protoplast of this cell divides many times and gives rise to several zoöspores that are haploid. Therefore reduction division takes place in the sporangia, which produce these zoöspores. These zoöspores produce sexual plants. In some species of *Ectocarpus* the alternation of generations is not as regular as that described.

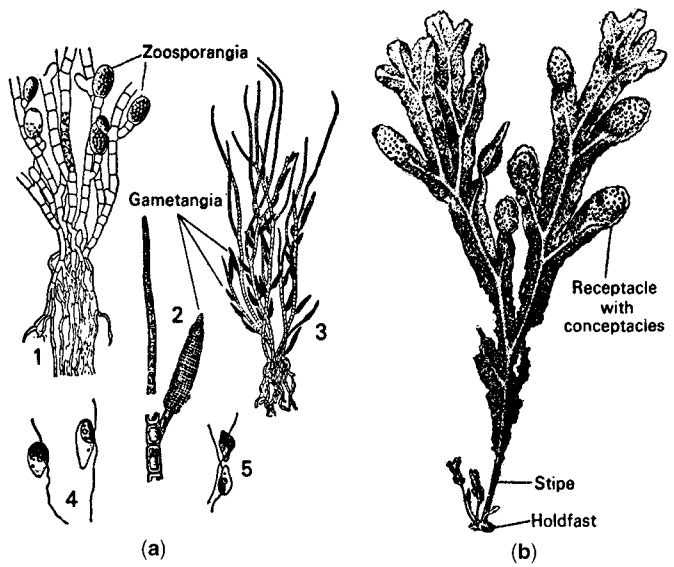

Fig. 6. (**a**) *Ectocarpus*. Stages in development: (1) sporophyte plant; (2,3) gametophyte plants; (4) two zoöspores; (5) conjugation of gametes to form zygotes. (Holman and Robbins, *Textbook of General Botany*, Wiley.) (**b**) *Fucus*. Mature plant. No bladders are shown. (*Morphologie und Biologie der Algen*, Gustav Fischer, Jena.)

Another order of brown algae is the Cutleriales, of which the genus *Cutleria* is a well-known example. In *Cutleria* the two generations have a very different appearance, the sexual plants being much branched, and several inches tall, while the asexual plants are small lobed thalli growing prostrate on the substratum. So different are these two generations that they are often mistaken for different plants. The sexual plants are of two kinds, male and female, which differ very little. The sex organs are borne on the surface of the thallus. The male gametangia are elongate structures borne on branching filaments; the female gametangia are more stout and composed of few cells. The male gametes are minute and biciliate; the female, also biciliate, are many times larger. Many male gametes swim to a single female, one fuses with it, producing a zygote. The zygote develops into an asexual plant. The zoöspores, formed from small sac-like zoösporangia, which develop in large numbers on the upper surface of the thallus, are biciliate and very similar to gametes. They form sexual plants. In this order there is a very distinct difference in the two gametes, male and female, and a striking difference between sexual and asexual plants.

A third order is the Laminariales, which includes the largest algae known, commonly known as kelps. Some of them have a very striking appearance. *Postelsia*, for example, has a plant body composed of an erect stiff stalk often several inches in diameter. From its base many thick root-like outgrowths spread out and fix the plant firmly to the substratum. At the top of the stalk, long spreading branches are found. When the plant is seen growing in water it has much the appearance of a palm tree, whence the common name, sea palm. Another plant in this order is *Chorda filum*. Its thallus is a tough cord-like object 3–8 feet (0.9 to 2.4 meters) long and about $\frac{1}{4}$ inch (0.6 centimeters) in diameter. It looks very much like a coarse round leather shoe string. A very common genus is *Laminaria*, which has many species of various forms, mostly large. Some of them consist of long cord-like stalks which bear at their upper end a broad flat expansion often 6–12 feet (1.8 to 3.6 meters) long and 8–15 inches (20.3 to 38.1 centimeters) broad. Colloquially these are known as devil's aprons. These large plants are the asexual generation and so are diploid. The zoösporangia are formed in immense numbers on the surface of the thallus. Each zoösporangium is a cylindrical object that produces many small biciliate zoöspores. These zoöspores swim down to the sea bed, where they develop into haploid or sexual plants. The latter are minute, usually consisting of a few cells which form a branching filament. Some of the plants are male, others female. In the female plant, any cell may become a sexual cell; often the plant is only a single cell. This sexual cell is an oögonium and forms a large non-motile egg that remains in the parent plant. Any cell of the male plant may become sexual, producing minute biciliate sperms, which swim to the egg and fuse with it, forming a zygote. The latter at once develops into an asexual plant. In this order, there is also a distinct alternation of generations, but the sexual generation contains the small plants, the asexual usually very large plants. The sexual cells are distinctly different: the large non-motile egg and the small biciliate sperm.

A fourth order of brown algae is the Fucales. Members of this order are tough, much-branched plants which are particularly abundant between the tide levels on rocky shores in regions where the water is cold. *Fucus*, the common rockweed or bladder wrack, is a common and well-known plant. In this, as in all members of this order, there is no asexual reproduction. Therefore no distinct alternation of generations can occur. A *Fucus* plant consists of a tough dichotomously branched frond, which is attached to the rock on which it grows by a disk-shaped holdfast. In many species hollow bladders develop along the frond and serve to bring the plant into an erect position at high tide. At the tips of the branches of the thallus the reproductive bodies, receptacles, are formed. In some species these tips are swollen to form hollow bladders, in others they are flat and little differentiated from the rest of the thallus. The reproductive cells are formed in spherical cavities connected with the surface by small pores. Each cavity is called a conceptacle. Numerous branching filaments rise from the lower part of the conceptacle wall. Branches of these filaments bear the sexual organs. In some species the two sexes are borne in the same receptacle, in others they occur on different plants. The male sex organs or antheridia are oval sacs. The protoplast of each sac divides to form 64 cells, each of

which becomes a laterally biciliate sperm. When mature these antheridia are extruded through the ostiole or opening of the conceptacle into the water. There the wall of the antheridium bursts, liberating the sperms. Each oögonium consists of a single cell. Its protoplast divides to form eight eggs. These also are extruded from the conceptacle, while still within the wall of the oögonium, and freed by the bursting of the same. Both types of conceptacle secrete a gelatinous matrix which surrounds the oögonia or antheridia and aids in bringing them to the surface of the receptacle. This matrix is squeezed out of the conceptacle by the partial drying of the frond at low tide. Each egg is a very large non-motile cell. Thousands of sperms are attracted to each egg and swim about it, causing it to revolve rapidly. Finally, one sperm gains entrance to the egg and fertilizes it. The other sperms immediately swim away. The fertilized egg settles to the bottom, attaches itself to the substratum and at once starts to develop into a new plant. In the Fucales there is no alternation of generations. The gametes of the Fucales are very distinct, one being a large non-motile egg, the other a very small swimming sperm. One is tempted to arrange the various orders of brown algae in a series showing the way in which each may have evolved. However, such evolutionary relationships are purely speculative and not supported by any real evidence. It is impossible to trace the ancestry of the brown algae back to any simple ancestor, since no simple forms of brown algae are known.

The economic importance of the brown algae, while slight, is much greater than that of the green algae. Large quantities of these plants are gathered and used for fertilizer, wherever agriculture is carried on near the coast. From the ash produced by burning the larger forms, the kelps and Fucales, iodine and also potassium are obtained. In the Orient and in some of the north Atlantic islands, some of the brown algae are used as food, both for human beings and for livestock.

The red algae or Rhodophyta form a very large group of plants, nearly all marine, of small to medium size. See Fig. 7. They are particularly abundant in warm coastal waters and are often plants of great beauty and extremely delicate habit. The red color to which they owe their name is caused by phycoerythrin, a red pigment present with the common chlorophyll-carotene group of pigments. These pigments are present in definite bodies or plastids, and not diffused through the protoplasts, as in the blue-green algae.

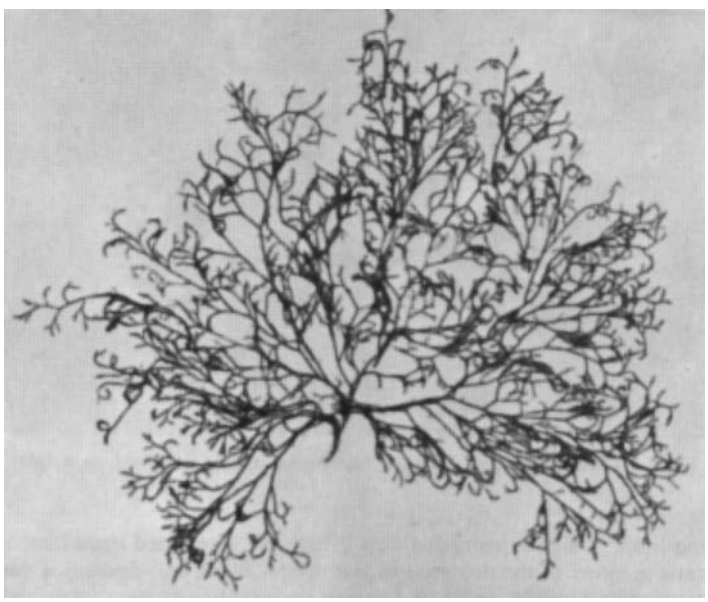

Fig. 7. Red algae. (*A.M. Winchester*.)

The forms of red algae are numerous. In many species the thallus is an extremely delicate filament. In other species the thallus is a tough, branched body 6–15 inches (15.2 to 38.1 centimeters) long. Others are flat membranes, which may be a single cell in thickness or may be many cells thick. Some are thickly covered with a calcareous deposit, so that they are hard and stony, resembling corals. No motile reproductive cells are produced by members of this group. In sexual reproduction there is always a large female cell which is fertilized by a small male cell. This sexual reproduction is a rather complicated process. The antheridia are single-celled bodies; in some species the whole cell is liberated, in others the protoplast of the antheridium is freed. In either case the male cell floats in the water, carried only by the current. The female reproductive organ is known as the procarp. In simpler forms this consists of a swollen basal portion called a carpogonium and a long slender portion called a trichogyne. Chance brings the male cell to the surface of the trichogyne, against which it sticks. The wall of the trichogyne is dissolved, allowing the nucleus of the male cell to enter the trichogyne. This nucleus passes down the trichogyne and enters the carpogonium, where it fuses with the female nucleus. From the fertilized carpogonium asexual spores called carpospores are formed, usually at the ends of branches, which grow out from the carpogonium or from cells which are formed from those surrounding the carpogonium. Into these carpospores, nuclei from the carpogonium pass. The carpospores of simpler red algae at once produce sexual plants. In most red algae, however, they produce asexual plants, which may be identical with the sexual plants in appearance. These asexual plants bear reproductive cells called tetraspores, because 4 of them are borne in a single sporangium. Each tetraspore gives rise to a sexual plant. So in the majority of red algae there is a distinct alternation of generations.

Of the many species of red algae very few are of any importance. In northern waters of both coasts of the Atlantic, dulse, *Rhodymenia palmata*, is found. It is gathered, cleaned more or less, and dried. It is then sold as a food or a relish. Species of *Porphyra*, often called laver, are also eaten, especially in Asia. Irish moss, or carrageen, which is *Chondrus crispus*, is another red alga gathered for food. See Fig. 8. It is a small much-branched plant, commonly dark red in color and with a beautiful iridescent surface. The plants are gathered, thoroughly cleaned and dried. Drying bleaches them to a creamy white color. When thoroughly dry they are bagged and sold. The powdered plant is commonly boiled in milk, flavored and sweetened, and allowed to cool. It forms a firm smooth gel known as blanc-mange. From species of red algae growing in the Pacific Ocean, agar is obtained.

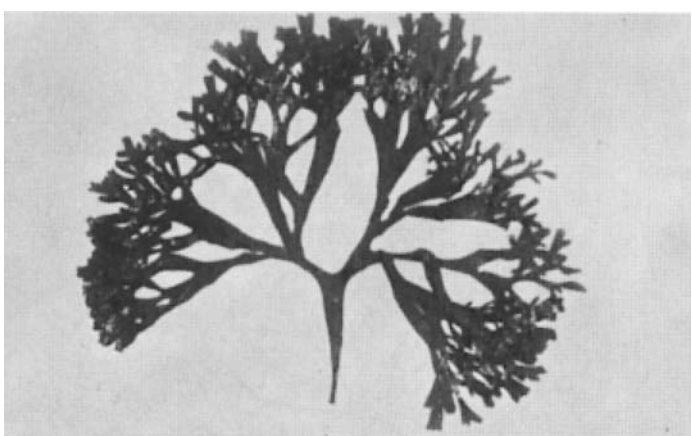

Fig. 8. *Chondrus crispus*. Frond. (*Photomicrograph by B.J. Ford; copyright.*)

The origin of the red algae and their relationships with other algae is a matter of considerable speculation. A few trace them from the blue-green algae, because in some of the more primitive red algae "connecting links" support this view. There are no ciliated reproductive cells in either of the two groups. But their distinct well-developed nucleus, their plastids, and their complex reproductive process set the red algae off very clearly. In view of these facts, it is perhaps more logical to derive the red algae from the green, using a form like *Coleochaete*.

ALGEBRA. 1. A generalization of arithmetic involving the study of relations between numbers represented by symbols and obtained by the operations of addition, subtraction, multiplication, division, raising to a power, and extracting a root. If only the first four operations are performed a finite number of times the resulting numbers, functions, or equations are rational; more precisely, rational integral or polynomial and rational fractional. When fractional powers and extraction of roots are also considered the quantities are irrational. A common problem in algebra is that of finding the value of an unknown satisfying an equation written in terms of the operations just stated. Other kinds of numbers, functions, or equations are not algebraic but transcendental.

2. An algebra over a field is defined as follows:

Let K be any field (in physical practice, usually a complex field) whose elements we shall call scalars. Let the set γ_{ijk}, with $i, j, k = 1, 2, \ldots, n$, be any n^3 elements of K. Then the set of all ordered n-tuples $(x_1, x_2, \ldots, x_n)$ of elements of K is called an algebra over K if addition, multiplication and scalar multiplication are defined thus:

$$(x_1, x_2, \ldots, x_n) + (y_1, y_2, \ldots, y_n)$$
$$= (x_1 + y_1, x_2 + y_2, \ldots, x_n + y_n)$$
$$(x_1, x_2, \ldots, x_n)(y_1, y_2, \ldots, y_n)$$
$$= (\gamma_{ij1} x_i y_j, \gamma_{ij2} x_i y_j, \ldots, \gamma_{ijn} x_i y_j)$$
$$\lambda(x_1, x_2, \ldots, x_n) = (\lambda x_1, \lambda x_2, \ldots, \lambda x_n)$$

where λ is a scalar and we have used the summation convention. Setting

$$l_1 = (1, 0, \ldots, 0), l_2 = (0, 1, \ldots, 0), \ldots, l_n$$
$$= (0, 0, \ldots, 1)$$

we have $(x_1, x_2, \ldots, x_n) = x_i l_i$, and $l_i l_j = \gamma_{ijk} l_k$. The l_i form a basis of the algebra and the γ_{ijk} are its structure constants.

3. An algebra of subsets of a set X is a class of subsets of X that contains the complement of each of its members and the union of any two of its members (or the intersection of any two of its members). An algebra of subsets is a Boolean algebra relative to the operations of union and intersection. (For definitions of union and intersection as used here, see **Boolean Algebra**.)

4. The algebra of a group is that of polynomials, with coefficients in a field K, of the elements $a_1, a_2, \ldots, a_n$ of a finite group G, where if

$$x = k_1 a_1 + k_2 a_2 + \cdots + k_n a_n$$
$$y = k_1' a_1 = k_2' a_2 + \cdots + k_n' a_n$$

then

$$x + y = (k_1 + k_1') a_1 + \cdots + (k_n + k_n') a_n$$

and

$$xy = l_1 a_1 + l_2 a_2 + \cdots + l_n a_n$$

where x and y have been multiplied together as polynomials, the product $a_i a_j$ being determined by the law of multiplication of the group. See also **Algebraic Equations**.

ALGEBRAIC EQUATIONS. An equation, or set of simultaneous equations, in which the unknowns occur as rational *functions* only. Hence the equations are expressible by equating polynomials to zero. Here the case of a single equation in one unknown is considered:

$$a_0 P(x) \equiv a_0 x^n + a_1 x^{n-1} + \cdots + a_n = 0, a_0 \neq 0$$

where the a_i do not depend upon x, and are called the coefficients of the equation, and n is the degree. This equation is equivalent to

$$P(x) \equiv x^n - c_1 x^{n-1} + \cdots + (-1)^n C_n = 0$$
$$c_i = (-1)^i a_i / a_0$$

where the c_i are the elementary symmetric functions of the roots x_i. See also **Symmetric Function**.

The *remainder theorem* states that if $a_0 P(x)$ is divided by $x - r$, the remainder is $a_0 P(r)$:

$$a_0 P(x) \equiv (x - r) Q(x) + a_0 P(r)$$

The *factor theorem* is a corollary and states that if r is a root of $P(x) = 0$, then $x - r$ divides $P(x)$. The "fundamental theorem of algebra" states that every algebraic equation has a root, real or complex. These theorems imply that $P(x)$ can be factored completely:

$$P(x) = (x - x_1)(x - x_2) \cdots (x - x_n)$$

each x_i being a root. If $x_i = x_j$ for some $i \neq$ j, then $x_i = x_j$ is a double root; if $x_i = x_j = x_k$, a triple root, ... Counting a root x_i of multiplicity m as being m coincident roots, one says that an algebraic equation of degree n has exactly n roots (neither more nor less).

A Taylor series expansion gives

$$P(x - r) = P(r) + (x - r) P'(r) + \cdots + (x - r)^n P^{(n)}(r)/n!$$

Hence r is a root of multiplicity m if and only if

$$0 = P(r) = P'(r) = \cdots = P^{(m-1)}(r) \neq P^{(m)}(r)$$

hence r satisfies the derived equations

$$P^{(i)}(x) = 0, \quad i = 0, 1, \ldots, m - 1$$

In general, setting $y = x - r$, if

$$b_i = P^{(n-i)}(r)/(n - 1)!$$

then any root of

$$y^n + b_1 y^{n-1} + \cdots + b_n = 0$$

is r less than a root x_i, hence the roots are said to have been reduced by r. Repeated synthetic division can be applied to the original equation to obtain the b_i since $b_n = P(r)$ is the remainder after dividing $P(x)$ by $x - r$; b_{n-1} that after dividing the quotient by $x - r$; .... See also **Synthetic Division**.

Other useful transformations are the following. The roots of

$$a_0 y^n - a_1 y^{n-1} + \cdots + (-1)^n a_n = 0$$

are the negatives of the roots of the original; those of

$$a_0 y^n + a_1 \alpha y^{n-1} + \cdots + a_n \alpha^n = 0$$

are α times the roots of the original; those of

$$a_n y^n + a_{n-1} y^{n-1} + \cdots + a_0 = 0$$

are the reciprocals of those of the original. These can be derived by setting $x = -y$, $x = y/\alpha$, and $x = 1/y$.

When the coefficients a_i are integers, then any rational root when expressed as a fraction p/q in lowest terms is such that p divides a_n and q divides a_0 without remainder. In particular, any integral root must be a divisor of a_n. In principle all rational roots can be found exactly, and once any root r is known, all other roots must satisfy $Q(x) = 0$ where $Q = P/(x - r)$. For irrational roots, see **Budan Theorem**; **Iterative Methods**; and **Newton's Formula for Interpolation**.

While these methods, except for Horner's, apply as well to complex roots as to real, it may be convenient to evaluate $P(z)$ with $z = x + iy$, and write

$$P(z) = R(x, y) + i J(x, y)$$

after collecting real and pure imaginary terms. Then

$$R(x, y) = J(x, y) = 0$$

are the two simultaneous equations in x and y, and any real solution (x, y) determines a complex solution $z = x + iy$ of $P(z) = 0$. See also **Bernoulli Method**.

ALGEBRAIC GEOMETRY. See **Geometry**.

ALGEBRAIC TOPOLOGY. See **Topology**.

ALGERIAN CURRENT. See **Ocean Currents**.

ALGICIDE. A substance, natural or synthetic, used for destroying or controlling algae. The term is also sometimes used to describe chemicals used for controlling aquatic vegetation, although these materials are more properly classified as aquatic herbicides. See **Herbicide**.

ALGIN. A hydrophilic colloidal polysaccharide obtained from several species of brown algae. The term is used both in reference to the pure substance, alginic acid, extracted from the algae and also to the salts of this acid such as sodium or ammonium alginate, in which forms it is used commercially. The alginates currently find a large number of applications in the paint, rubber, pharmaceutical, food, and other industries. See also **Gums and Mucilages**.

ALGINATES. See **Food Additives**.

ALGOL (β Persei). One of the first variable stars to be recognized as such. The first scientific notice of this variability was made by Montanari in 1670, but it is quite evident that the changes in the light of this star were noticed long before then. The name Algol, which signifies "demon star" probably was suggested because of the star's peculiar behavior. Algol is an eclipsing binary and the first star of this type to be explained. Because of its great brightness, it has been extensively observed with all types of stellar photometers, and the characteristics of its light curve are known. Algol is also a spectroscopic binary and, from the determination of the orbital elements from light variability as well as from the spectroscopic data, the physical characteristics of the component parts may be determined. See also **Binary Stars**; **Eclipsing Binary**; and **Spectroscopic Binaries**.

ALGONKIAN. A term applied to rock formations of late pre-Cambrian (Proterozoic) date in the Great Lakes region, and to the unit of time represented by these formations. Some American geologists use the term as a synonym for late pre-Cambrian.

ALGORITHM. The word algorithm is derived from the name of a Persian mathematician called Abu Ja'far Mohammed ibn Mûsâ al-Khowârizmî, who lived in the ninth century and is credited with providing the step-by-step rules for adding, subtracting, multiplying, and dividing ordinary decimal numbers. Al-Khow ârizmî also wrote the book Kitab al jabr wa'l-muqabala; the word algebra is derived from the title of this book. One of the earliest machines credited with executing what it might be called an algorithm was the weaving loom invented by Joseph Jacquard around 1801. The weaving process was controlled by punch cards — cards with holes punched at various locations. These holes, when sensed by a special mechanism, selected the threads and controlled some other actions of the machine. Another early implementation of an algorithm is due to Herman Hollerith, an American engineer, who invented a tabulating machine to process the U.S. national census of 1890. Hollerith's machine also used punched cards. Some of the most fundamental theoretical work concerning the capabilities and limitations of executing algorithms on a machine were developed around the 1930s by Alan Turing, Alonzo Church, Emil Post, and Kurt Gödel. The first algorithms implemented in a computer were developed around 1940. Among the most relevant figures that helped develop the concept of a program as we currently know it are Alan Turing, Howard Aiken, John Mauchly, J. Presper Eckert, and John Von Neuman. See also **Hollerith**; and **Turing Machine**.

The notion of an algorithm is essential to the understanding of computer programming. By an algorithm we understand any finite sequence of instructions that allows us to perform a specific task. The idea of an algorithm has been known since the dawn of mathematics. For example, Euclid, the Greek mathematician, devised one of the earliest known mathematical algorithms. Euclid's algorithm allows us to find the greatest common divisor of two given positive integer numbers. When an algorithm is implemented in a computer language the algorithm is called a program. The process of carrying out the instructions of an algorithm is known as "executing" the algorithm. Algorithms, whether implemented in a computer or not, must satisfy the following characteristics: 1) Finiteness. That is, an algorithm must terminate after a finite number of steps. Notice, however, that the number of steps can be quite large. When executed in a computer some algorithms may take several weeks or even months before they finish. 2) Definiteness. That is, every step of the algorithm must be unambiguously defined. In other words, there must not be any misunderstanding as to what is required from every step of the algorithm. 3) Input. An algorithm may have zero or more inputs. By the latter term we mean the data that are given to the algorithm before the algorithm begins its execution. 4) Output. An algorithm must have one or more outputs. By the latter term we will refer to the result or results produced by the algorithm. If an algorithm produces the correct result, the algorithm is said to have been executed successfully; otherwise it is said to be unsuccessful. 5) Effectiveness. This characteristic requires that all steps of the algorithm be sufficiently basic that, in theory, a person using paper and pencil can carry them out provided that that person has enough time to do it.

Algorithms are generally classified according to the function that they perform, for example, searching and sorting, or the type of operation for which they are designed, for example, mathematical or string manipulations algorithms. The area of computer science and mathematics that studies the time that it takes algorithms to execute or the amount of memory space that they require is generally called analysis of algorithms.

Algorithms are particularly important where a formerly analog data collection and processing system has changed over to digital methodologies. This has been a frequent occurrence during the last several years, resulting from digital computerization. An excellent example is found in process instrumentation and control and in industrial automation systems. The conversion requires an appropriate software architecture and the matching of digital algorithms to analog behavior.

Whereas the analog controller continuously sensed the process state and manipulated the actuators, the digital controller must repeatedly sample the state, convert it to a quantified number, use that number to compute control actions, and output those actions. Each of these steps involves inherent problems and errors.

Standard digital control texts address the sampling problem but treat the broader control design in terms of neutral, computed parameters not clearly related to the process gains and time constants. Process control depends on standard control algorithms, whose parameters may be set or tuned in terms of known process properties.

The detailed calculation of process control algorithms is beyond the scope of this *Encyclopedia*. The details are well covered in the Bristol article listed.

ALIASING ERROR (Data Acquisition System). The Shannon-Nyquist sampling theorem states that in order to reconstruct a signal containing frequency components in the spectrum 0 to f_m Hz from sampled data, samples must be taken at a rate of at least $2f_m$ samples per second. Failure to obtain data at this rate converts high-frequency components into low-frequency components. Thus, the reconstructed signal contains low-frequency energy not present in the original signal. Figure 1 illustrates a 5-Hz signal sampled at a 4-samples-per-second rate. The reconstructed signal has a frequency of 1 Hz. An *aliasing error* is an

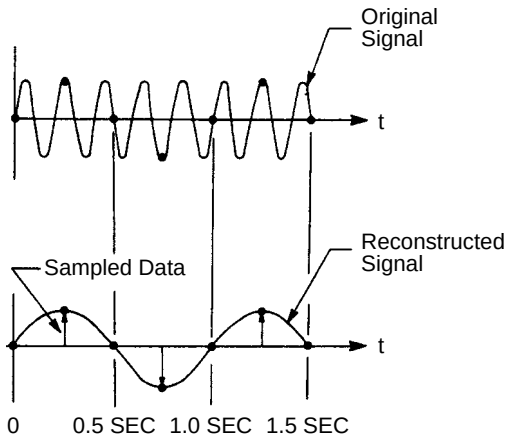

Fig. 1. Example of aliasing error in a sampled-data system.

error that can be introduced into sampled data in a digital-data-acquisition system as the result of violation of the basic sampling theorem.

The term *aliasing* results from the interpretation that the high-frequency components take the "alias" of a lower-frequency component. An equivalent term, *folding error*, arises from the interpretation that the frequency spectrum of the signal is folded such that high-frequency components appear in a lower-frequency spectrum.

Sampling a continuous signal is equivalent to modulating the signal with a series of uniformly spaced impulses as indicated in Fig. 2. If a signal containing frequency components up to a frequency f_m is modulated by a carrier of frequency f_s, the frequency spectrum of the resulting sampled signal consists of the original spectrum, plus harmonic spectra centered on the sampling frequency and its harmonics as shown in Fig. 1. This is the same effect as the modulation of an rf carrier with an audio signal in amplitude-modulated radio, except that there are an infinite number of carrier frequencies because the frequency spectrum of a train of equally spaced impulses (the modulating signal) consists of an infinite number of frequency components at f_s and its harmonics.

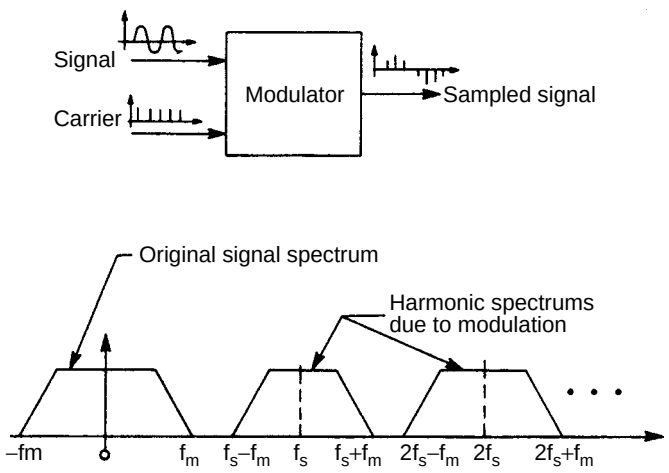

Fig. 2. Frequency-domain sampled spectra.

Figure 1 shows that if the sample frequency f_s is less than $2f_m$ the lower sideband of the first-harmonic spectrum overlaps the original signal spectrum. Inasmuch as mathematical signal-reconstruction methods are equivalent to low-pass filtering in the signal domain, it is evident that the signal energy from the first-harmonic spectrum that overlaps the original spectrum will be passed by the low-pass filter and, therefore, will affect the nature of the reconstructed signal.

In the foregoing description, the signal was assumed to have no frequency components above the frequency f_m. In practice, signals are not definitively band-limited and high-frequency components are present in any real signal. In the majority of process-control applications, the signals are nominally band-limited by the low-pass characteristics of the process or the signal transducers. In connection with such signals, the sampling theorem frequently is stated so as to require sampling at twice the highest *significant* signal frequency. In practice, selection of the sampling frequency depends upon the interpretation of the term *significant*. A rule of thumb is that the sampling rate should be 5 to 10 times the highest frequency of interest. Although not technically perfect, the rule is valuable inasmuch as signals are usually band-limited to reject frequencies above those of interest. The 5 or 10 multiplier provides a safety factor to account for the finite rolloff rate of most low-pass systems. Where accurate reconstruction of the sampled signal is needed, an estimate of the aliasing error should be made.

An estimate of the aliasing error can be made by using a graphical technique, based on a frequency-spectrum diagram of the type shown in Fig. 2. The frequency spectrum of the original signal and the spectra of the modulation harmonics are drawn as indicated. At each frequency in the bandpass of the reconstruction filter or its mathematical equivalent, the amplitude of the original frequency components and all contributions from aliased harmonics are summed. This sum is an estimate of the magnitude of this frequency component in the reconstructed signal. The estimate is conservative inasmuch as the true contribution is represented by the vector sum of the components, whereas the estimate is based upon the algebraic sum.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ALIDADE. See **Meteorology**.

ALIENATION (Coefficient of). A term occurring in psychology. If the coefficient of correlation between two variables is r, the coefficient of alienation is defined as $(1 - r^2)^{1/2}$.

ALIGNMENT CHART. Nomograms or calculating charts used to represent formulas containing three or more variables. Graduated lines represent the variables; an index line or isopleth passing through points of two scales of known values will intersect the third scale to give the solution of the problem. The nomogram shown in Fig. 1 will give the solution of the equation $0.785D^2S = T$, where D is the root diameter of an American Standard screw, S is the unit tensile strength, and T is the total stress.

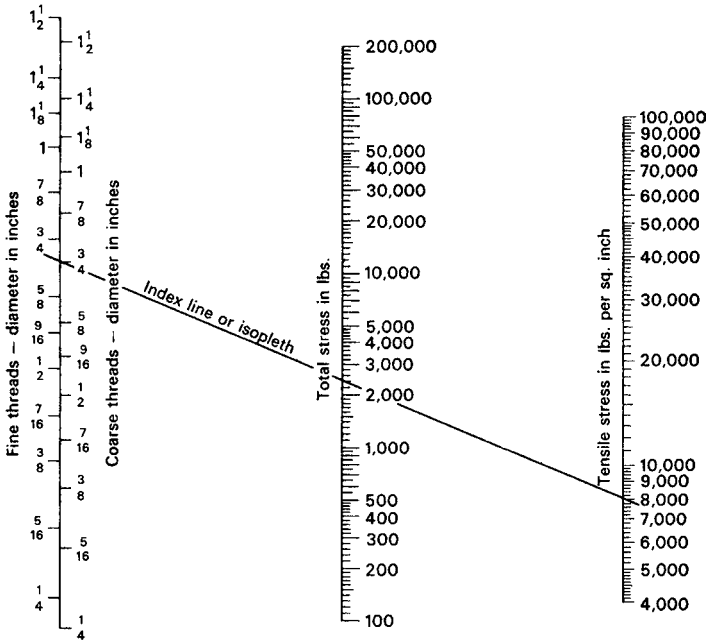

Fig. 1. Nomogram for calculating thread diameter and tensile strength and total stress for American Standard screws.

In addition to the accompanying three-parallel-line chart, alignment charts may take other forms, such as straight lines forming a Z shape, or the lines may be curved. The type of chart depends on the form of the mathematical equation represented.

ALIMENTARY TRACT. The structures through which nourishment passes during the process of digestion and elimination. These include the mouth, pharynx, esophagus, stomach, the small intestine, which includes duodenum, jejunum, and ileum, and the large intestine, which includes the cecum, colon, rectum, and anus. See also diagram under **Digestive System (Human)**.

ALIMENTATION. In glaciology, the combined processes that serve to increase the mass of a glacier or snowfield; the opposite of ablation. The deposition of snow is the major form of glacial alimentation, but other forms of precipitation, along with sublimation, re-freezing of melted water, etc., also contribute. The additional mass produced by alimentation is termed accumulation.

ALIPHATIC COMPOUND. An organic compound that can be regarded as a derivative of methane, CH_4. Most aliphatic compounds are open carbon chains, straight or branched, saturated or unsaturated. Originally, the term was used to denote the higher (fatty) acids of the $C_nH_{2n}O_2$ series. The word is derived from the Greek term for oil. See also **Compound (Chemical)**; and **Organic Chemistry**.

ALITAME. See **Sweeteners**.

ALKALI. A term that was originally applied to the hydroxides and carbonates of sodium and potassium but since has been extended to include the hydroxides and carbonates of the other alkali metals and ammonium. Alkali hydroxides are characterized by ability to form soluble soaps with fatty acids, to restore color to litmus which has been reddened by acids, and to unite with carbon dioxide to form soluble compounds. See also **Acids and Bases**.

ALKALI METALS. The elements of group 1 of the periodic classification. In order of increasing atomic number, they are hydrogen, lithium, sodium, potassium, rubidium, cesium, and francium. With the exception of hydrogen, which is a gas and which frequently imparts a quality of acidity to its compounds, the other members of the group display rather striking similarities of chemical behavior, all reactive with H_2O to form strongly alkaline solutions. The elements in the group, including hydrogen, are characterized by a valence of one, having one electron in an outer shell available for reaction. Because of their chemical similarities, these elements, along with *ammonium* and sometimes magnesium, are considered the sixth group in classical qualitative chemical analysis separations.

ALKALINE EARTHS. The elements of group 2 of the periodic classification. In order of increasing atomic number, they are beryllium, magnesium, calcium, strontium, barium, and radium. The members of the group display rather striking similarities of chemical behavior, including stable oxides and carbonates, with hydroxides that are less alkaline than those of group 1. The elements of the group are characterized by a valence of two, having two electrons in an outer shell available for reaction. Because of their chemical similarities, these elements are considered the fifth group in classical qualitative chemical analysis separations.

ALKALINITY. The relative acidity of any solution expressed in a pH range of numbers. The pH value is the negative common logarithm of the hydrogen-ion concentration in a solution, expressed in moles per liter of solution. A neutral solution, that is, one that is neither acidic nor alkaline, such as pure water, has a concentration of 10 moles per liter; its pH is thus 7. Acidic solutions have pH values ranging with decreasing acidity from 0 to nearly 7; alkaline or basic solutions have a pH ranging with increasing alkalinity from just beyond 7 to 14. In seawater, the alkalinity is a measure of the excess of hydroxyl ions over hydrogen ions, generally expressed as milliequivalents per liter. See also **pH (Hydrogen Ion Concentration)**.

ALKALI ROCKS. Igneous rocks which contain a relatively high amount of alkalis in the form of soda amphiboles, *soda* pyroxenes, or felspathoids, are said to be alkaline, or alkalic. Igneous rocks in which the proportions of both lime and alkalis are high, as combined in the minerals, feldspar, hornblende, and augite, are said to be calcalkalic.

ALKALOIDS. The term, alkaloid, which was first proposed by the pharmacist, W. Meissner, in 1819, and means "alkali-like," is applied to basic, nitrogen-containing compounds of plant origin. Two further qualifications usually are added to this definition: (1) the compounds have complex molecular structures; and (2) they manifest significant pharmacological activity. Such compounds occur only in certain genera and families, rarely being universally distributed in larger groups of plants. Many widely distributed bases of plant origin, such as methyltrimethyl-and other open-chain simple alkylamines, the cholines, and the phenylalkylamines, are not classed as alkaloids. Alkaloids usually have a rather complex structure with the nitrogen atom involved in a heterocyclic ring. However, thiamine, a heterocyclic nitrogenous base, is not regarded as an alkaloid mainly because of its almost universal distribution in living matter. Colchicine, on the other hand, is classed as an alkaloid even though it is not basic and its nitrogen atom is not incorporated into a heterocyclic ring. It apparently qualifies as an alkaloid because of its particular pharmacological activity and limited distribution in the plant world.

Over 2000 alkaloids are known and it is estimated that they are present in only 10–15% of all vascular plants. They are rarely found in cryptogamia (exception, ergot alkaloids), gymnosperms, or monocotyledons. They occur abundantly in certain dicotyledons and particularly in the following families: *Apocynaceaae* (dogbane, quebracho, pereiro bark); *Papaveraceae* (poppies, chelidonium); *Papilionaceae* (lupins, butterfly-shaped flowers); *Ranunculaceae* (aconitum, delphinium); *Rubiaceae* (cinchona bark, ipecacuanha); *Rutaceae* (citrus, fagara); and *Solanaceae* (tobacco, deadly nightshade, tomato, potato, thorn apple). Well-characterized alkaloids have been isolated from the roots, seeds, leaves or bark of some 40 plant families. *Papaveraceae* is an unusual family, in that all of its species contain alkaloids.

Brief descriptions in alphabetical order of alkaloids of commercial or medical importance or of societal concern (alkaloid narcotics) are given later in this entry. See also **Amphetamine**; **Morphine**; and **Pyridine and Derivatives**.

The nomenclature of alkaloids has not been systemized, both because of the complexity of the compounds and for historical reasons. The two commonly used systems classify alkaloids either according to the plant genera in which they occur, or on the basis of similarity of molecular structure. Important classes of alkaloids containing generically related members are the aconitum, cinchona, ephedra, lupin, opium, rauwolfia, senecio, solanum, and strychnos alkaloids. Chemically derived alkaloid names are based upon the skeletal feature which members of a group possess in common. Thus, indole alkaloids (e.g., psilocybin, the active principle of Mexican hallucinogenic mushrooms) contain an indole or modified indole nucleus, and pyrrolidine alkaloids (e.g., hygrine) contain the pyrrolidine ring system. Other examples of this type of classification include the pyridine, quinoline, isoquinoline, imidazole, pyridine-pyrrolidine, and piperidine-pyrrolidine type alkaloids. Several alkaloids are summarized along these general terms in Table 1.

The beginning of alkaloid chemistry is usually considered to be 1805 when F.W. Sertürner first isolated morphine. He prepared several salts of morphine and demonstrated that it was the principle responsible for the physiological effect of opium. Alkaloid research has continued to date, but because most likely plant sources have been investigated and because a large number of synthetic drugs serve medical and other needs more effectively, the greatest emphasis has been placed upon the synthetics.

Sometimes, there is confusion between alkaloids and narcotics. It should be stressed that all alkaloids are not narcotics; and all narcotics are not alkaloids. A narcotic has the general definition of a drug that produces sleep or stupor, and also relieves pain. Many alkaloids do not meet these specifications.

The molecular complexity of the alkaloids is demonstrated by Fig. 1. Alkaloids react as bases to form salts. The salts used especially for crystallization purposes are the hydrochlorides, sulfates, and oxalates, which are generally soluble in water or alcohol, insoluble in ether, chloroform, carbon tetrachloride, or amyl alcohol. Alkaloid salts unite with mercury, gold, and platinum chlorides. Free alkaloids lack characteristic color reactions but react with certain reagents, as follows, with (1) iodine in potassium iodide solution, forming chocolate brown precipitate; (2) mercuric iodide in potassium iodide solution (potassium mercuriiodide), forming precipitate; (3) potassium iodobismuthate, forming orange-red precipitate; (4) bromine-saturated concentrated hydrobromic acid forming yellow precipitate; (5) tannic acid, forming precipitate; (6) molybdophosphoric acid, forming precipitate; (7) tungstophosphoric

TABLE 1. GENERAL CLASSIFICATION OF ALKALOIDS

General Class	Examples
Derivatives of aryl-substituted amines	Adrenaline, amphetamine, ephedrine, phenylephrine tyramine
Derivatives of pyrrole	Carpaine, hygrine, nicotine
Derivatives of imidazole	Pilocarpine
Derivatives of pyridine and piperidine	Anabasine, coniine, ricinine
Containing fusion of two piperidine rings	Isopelletierine, pseudopelletierine
Pyrrole rings fused with other rings	Gelsemine, physostigmine, vasicine, yohimbine
Aporphone alkaloids	Apomorphine corydine, isothebaine
Berberine alkaloids	Berberine, emetine
Bis-benzylisoquinoline alkaloids	Bebeering, trilobine
Cinchona alkaloids	Cinchonine, quinidine, quinine
Cryptopine alkaloids	Cryptopine, protopine
Isoquinoline alkaloids	Anhalidine, pellotine, sarsoline
Lupine alkaloids	Lupanine, sparteine
Morphine and related alkaloids	Codeine, morphine, thebaine
Papaverine alkaloids	Codamine, homolaudanosine, papeverine
Phthalide isoquinoline alkaloids (also known as narcotine alkaloids)	Hydrastine, narceine, narcotine
Quinoline alkaloids	Dictamine, galipoline, lycorine
Tropine alkaloids	Atropine, cocaine, ecgonine, scopolamine, tropine
Other alkaloids	Brucine, sclanidine, strychnine

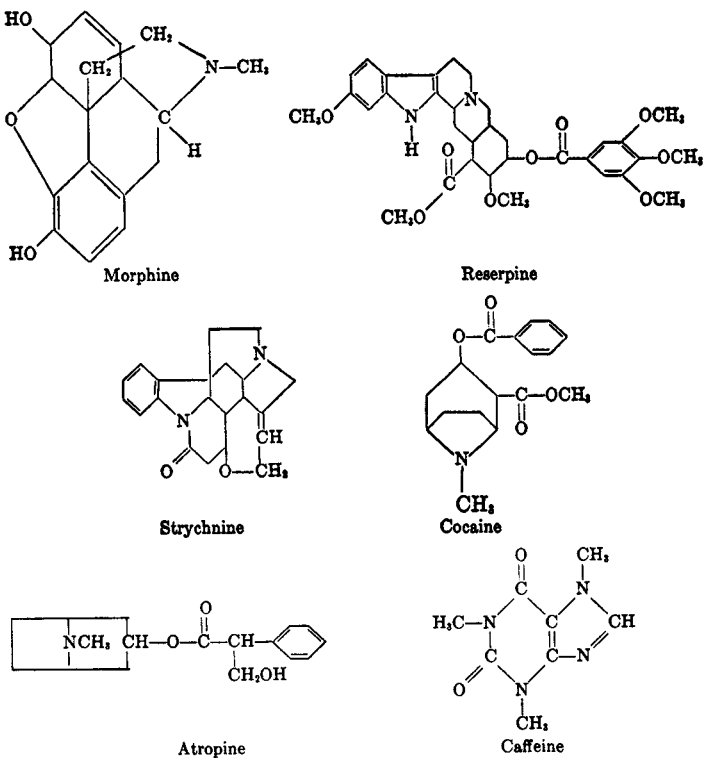

Fig. 1. Structures of representative alkaloids. The carbon atoms in the rings and the hydrogen atoms attached to them are not designated by letter symbols. However, there is understood to be a carbon atom at each corner (except for the cross-over in the structure of morphine) and each carbon atom has four bonds, so that any bonds not shown or represented by attached groups are joined to hydrogen atoms.

acid, forming precipitate; (8) gold(III) chloride, forming crystalline precipitate of characteristic melting point; (9) platinum(IV) chloride, forming crystalline precipitate of characteristic melting point; (10) picric acid, forming precipitate; (11) perchloric acid, forming precipitate. Many alkaloids form more or less characteristic colors with acids, solutions of acidic salts, etc.

The function of alkaloids in the source plant has not been fully explained. Some authorities simply regard them as by-products of the plant metabolism. Others conceive of alkaloids as reservoirs for protein synthesis; as protective materials discouraging animal or insect attacks; as plant stimulants or regulators in such activities as growth, metabolism, and reproduction; as detoxifying agents, which render harmless (by processes such as methylation, condensation, and ring closure) substances whose accumulation might otherwise cause damage to the plant. While these theories are of interest, it is also of interest to observe that from 85–90% of all plants manage well without the presence of alkaloids in their structures.

Adrenaline®. See **Epinephrine** later in this entry.

Atropine, [CAS: 51-55-8] also known as daturine, $C_{17}H_{23}NO_3$ (see structural formula in accompanying diagram), white, crystalline substance, optically inactive, but usually contains levorotatory hyoscyamine. Compound is soluble in alcohol, ether, chloroform, and glycerol; slightly soluble in water; mp 114–116 °C. Atropine is prepared by extraction from *Datura stramonium*, or synthesized. The compound is toxic and allergenic. Atropine is used in medicine and is an antidote for cholinesterase-inhibiting compounds, such as organophosphorus insecticides and certain nerve gases. Atropine is commonly offered as the sulfate. Atropine is used in connection with the treatment of disturbances of cardiac rhythm and conductance, notably in the therapy of sinus bradycardia and sick sinus syndrome. Atropine is also used in some cases of heart block. In particularly high doses, atropine may induce ventricular tachycardia in an ischemic myocardium. Atropine is frequently one of several components in brand name prescription drugs.

Caffeine, [CAS: 58-08-2] also known as theine, or methyltheobromine, 1,2,7-trimethyl xanthine (see structural formula in Fig. 1), white, fleecy or long, flexible crystals. Caffeine effloresces in air and commences losing water at 80 °C. Soluble in chloroform, slightly soluble in water and alcohol, very slightly soluble in ether, mp 236.8 °C, odorless, bitter taste. Solutions are neutral to litmus paper.

Caffeine is derived by extraction of coffee beans, tea leaves, and kola nuts. It is also prepared synthetically. Much of the caffeine of commerce is a by-product of decaffeinized coffee manufacture. See also **Coffee Tree and Coffee**. The compound is purified by a series of recrystallizations. Caffeine finds use in medicine and in soft drinks. Caffeine is also available as the hydrobromide and as sodium benzoate, which is a mixture of caffeine and sodium benzoate, containing 47–50% anhydrous caffeine and 50–53% sodium benzoate. This mixture is more soluble in water than pure caffeine. A number of nonprescription (pain relief) drugs contain caffeine as one of several ingredients. Caffeine is a known cardiac stimulant and in some persons who consume significant amounts, caffeine can produce ventricular premature beats.

Cocaine [CAS: 50-36-2] (also known as methylbenzoylepgonine), $C_{17}H_{21}NO_4$, is a colorless-to-white crystalline substance, usually reduced to powder. Cocaine is soluble in alcohol, chloroform, and ether, slightly soluble in water, giving a solution slightly alkaline to litmus. The hydrochloride is levorotatory, mp 98 °C. Cocaine is derived by extraction of the leaves of coca (*Erythroxylon*) with sodium carbonate solution, followed by treatment with dilute acid and extraction with ether. The solvent is evaporated after which the substance is re-dissolved and subsequently crystallized. Cocaine also is prepared synthetically from the alkaloid ecgonine. Cocaine is *highly toxic* and *habit -forming*. While there are some medical uses of cocaine, usage must always be under the direction of a physician. It is classified as a narcotic in most countries. Society's major concern with cocaine is its use (increasing in recent years) as a narcotic.

Cocaine has been known as a very dangerous material since the early 1900s. When use of it as a narcotic increased during the early 1970s, serious misconceptions concerning its "safety" as compared with many other narcotics led and continue to lead to many deaths from its use.

Addicts use cocaine intravenously or by snorting the powder. After intravenous injections, coma and respiratory depression can occur rapidly. It has been reported that fatalities associated with snorting usually occur shortly after the abrupt onset of major motor seizures, which may develop within minutes to an hour after several nasal ingestions. Similar results occur if the substance is taken by mouth. Treatment is directed toward ventilatory support and control of seizures — although in many instances a victim may not be discovered in time to prevent death. It is interesting to note that cocaine smugglers, who have placed cocaine-filled condoms in their rectum or alimentary tract, have died (Suarez et al., 1977). The structural formula of cocaine is given in Fig. 1.

Codeine, [CAS: 76-57-3] also known as methylmorphine, $C_{18}H_{21}NO_3 \cdot H_2O$, is a colorless white crystalline substance, mp 154.9 °C, slightly soluble in water, soluble in alcohol and chloroform, effloresces slowly in dry air. Codeine is derived from opium by extraction or by the methylation of morphine. For medical use, codeine is usually offered as the dichloride, phosphate, or sulfate. Codeine is *habit forming*. Codeine is known to exacerbate *urticaria* (familiarly known as *hives*). Since codeine is incorporated in numerous prescription medicines for headache, heartburn, fatigue, coughing, and relief of aches and pains, persons with a history of urticaria should make this fact known to their physician. Codeine is sometimes used in cases of acute *pericarditis* to relieve severe chest pains in early phases of disease. Codeine is sometimes used in drug therapy of renal (kidney) diseases.

Colchicine, [CAS: 64-86-8] an alkaloid plant hormone, $C_{22}H_{25}NO_6$, is yellow crystalline or powdered, nearly odorless, mp 135–150 °C, soluble in water, alcohol, and chloroform, moderately soluble in ether. Solutions are levorotatory and deteriorate under light. The substance is highly toxic (0.02 gram may be fatal if ingested). Colchicine is extracted from the plant *Colchicum autumnale* after which it is crystallized. The compound also has been synthesized. Biologists have used colchicine to induce chromosome doubling in plants. Colchicine finds a number of uses in medicine.

Although colchicine has been known for many years, interest in the drug has been revitalized in recent years as the result of the discovery that it interferes with cell division by destroying the spindle mechanism. The two chromatids, which represent one chromosome at the metaphase stage, fail to separate and do not migrate to the poles (ends) of the cell. Each chromatid becomes a chromosome in situ. The entire group of new chromosomes now forms a resting nucleus and the next cell division reveals twice as many chromosomes as before. The cell has changed from the diploid to the tetraploid condition. Applied to germinating seeds or growing stem tips in concentrations of about 1 gram in 10,000 cubic centimeters of water for 4 or 5 days, colchicine may thus double the chromosome number of many or all of the cells, producing a tetraploid plant or shoot. Offspring from such plants may be wholly tetraploid and breed true. Tetraploid plants are larger than diploid plants and often more valuable. The alkaloid has also been used to double the chromosome number of sterile hybrids produced by crossing widely separated species of plants. Such plants, after colchicine treatment, contain in each cell two complete diploid sets of chromosomes, one from each of the parent species, and become fertile, pure-breeding hybrid species.

In medicine, colchicine is probably best known for its use in connection with the treatment of gout. Acute attacks of gout are characteristically and specifically aborted by colchicine. The response noted after administration of the drug also can be useful in diagnosing gout cases where synovial fluid cannot be aspirated and examined for the presence of typical urate crystals. However, colchicine does not affect the course of acute synovitis in rheumatoid arthritis.

Kaplan (1960) observed that colchicine may produce objective improvement in the periarthritis associated with *sarcoidosis* (presence of noncaseating granulomas in tissue). Colchicine is sometimes used in the treatment of *scleroderma* (deposition of fibrous connective tissues in skin or other organs); it may assist in preventing attacks of Mediterranean fever; and it is sometimes used as part of drug therapy for some renal (kidney) diseases.

Colchicine can cause diarrhea as the result of mucosal damage and it has been established that colchicine interferes with the absorption of vitamin B_{12}.

Emetine, [CAS: 316-42-7] an alkaloid from ipecac, $C_{29}H_{40}O_4N_2$, is a white powder, mp 74 °C, with a very bitter taste. The substance is soluble in alcohol and ether, slightly soluble in water. Emetine darkens upon exposure to light. The compound is derived by extraction from the root of *Cephalis ipecacuanha* (ipecac). It is also made synthetically. Medically, ipecac is useful as an emetic (induces vomiting) for emergency use in the treatment of drug overdosage and in certain cases of poisoning. Ipecac should not be administered to persons in an unconscious state. It should be noted that emesis is not the proper treatment in all cases of potential poisoning. It should not be induced when such substances as petroleum distillates, strong alkali, acids, or strychnine are ingested.

Ephedrine, [CAS: 299-42-3] 1-phenyl-2-methylaminopropanol, $C_6H_5CH(OH)CH(NHCH_3)CH_3$, is a white-to-colorless granular substance, unctuous (greasy) to the touch, and hygroscopic. The compound gradually decomposes upon exposure to light. Soluble in water, alcohol, ether, chloroform, and oils, mp 33–40 °C, by 255 °C, and decomposes above this temperature. Ephedrine is isolated from stems or leaves of *Ephedra*, especially Ma huang (found in China and India). Medically, it is usually offered as the hydrochloride. In the treatment of bronchial asthma, ephedrine is known as a *beta agonist*. Compounds of this type reduce obstruction by activating the enzyme adenylate cyclase. This increases intracellular concentrations of cAMP (cyclic 3′5′-adenosine monophosphate) in bronchial smooth muscle and mast cells. Ephedrine is most useful for the treatment of mild asthma. In severe asthma, ephedrine rarely maintains completely normal airway dynamics over long periods. Ephedrine also has been used in the treatment of cerebral transient ischemic attacks, particularly with patients with vertabrobasilar artery insufficiency who have symptoms associated with relatively low blood pressure, or with postural changes in blood pressure. Ephedrine sulfate also has been used in drug therapy in connection with urticaria (hives).

Epinephrine, [CAS: 51-43-4] a hormone having a benzenoid structure, $C_9H_{13}O_3N$, also called adrenaline. It can be obtained by extraction from the adrenal glands of cattle and also prepared synthetically. Its effect on body metabolism is pronounced, causing an increase in blood pressure and rate of heartbeat. Under normal conditions, its rate of release into the system is constant, but emotional stresses, such as fear or anger rapidly increase the output and result in temporarily heightened metabolic activity. Epinephrine is used for the symptomatic treatment of bronchial asthma and reversible bronchospasm associated with chronic bronchitis and emphysema. The drug acts on both alpha and beta receptor sites. Beta stimulation provides bronchodilator action by relaxing bronchial muscle. Alpha stimulation increases vital capacity by reducing congestion of the bronchial mucosa and by constricting pulmonary vessels.

Epinephrine is also used in the management of anesthetic procedures in connection with noncardiac surgery of patients with active ischemic heart disease. The drug is useful in the treatment of severe urticarial (hives) attacks, especially those accompanied by angioedema.

Epinephrine has numerous effects on intermediary metabolism. Among these are promotion of hepatic glycogenolysis, inhibition of hepatic gluconeognesis, and inhibition of insulin release. The drug also promotes the release of free fatty acids from triglyceride stores in adipose tissues. Epinephrine produces numerous cardiovascular effects. Epinephrine is particularly useful in treating conditions of immediate hypersensitivity — interactions between antigen and antibody. These mechanisms cause attacks of anaphylaxis, hay fever, hives and allergic asthma. Anaphylaxis can occur after bee and wasp stings, venoms, etc. Although the mechanism is not fully understood, epinephrine can play a lifesaving role in the treatment of acute systemic anaphylaxis.

In some instances, epinephrine can be a cause of a blood condition involving the leukocytes and known as neutrophilia. In very rare cases, an intramuscular injection of epinephrine can be a cause of clostridial myonecrosis (gas gangrene).

Heroin, [CAS: 561-27-3] diacetylmorphine $C_{17}H_{17}NO(C_2H_3O_2)_2$, is a white, essentially odorless, crystalline powder with bitter taste, soluble in alcohol, mp 173 °C. Heroin is derived by the acetylization of morphine. The substance is highly toxic and is a habit-forming narcotic. One-sixth grain (0.0108 gram) can be fatal. Although emergency facility personnel in some areas during recent years have come to regard heroin overdosage as approaching epidemic statistics, it is nevertheless estimated that the majority of persons with heroin overdose die before reaching a hospital. The initial crisis of an overdose is a severe respiratory depression and sometimes *apnea* (cessation of breathing). In emergency situations, the victim may be ventilated with a self-inflating resuscitative bag with delivery of 100% oxygen. Then, an endotracheal tube attached to a mechanical ventilator may be inserted. Naloxone (*Narcan*®), a narcotic antagonist, then may be administered intraveneously, often with repeated dosages over short intervals, until an improvement is noted in the respiratory rate or sensorial level of the victim. If a victim does not respond, this is usually indication that the situation is not opiate-related, or that other drugs also have been taken. Inasmuch as the antagonizing action of naloxone persists for only a few hours, a heroin overdose patient should be observed in the hospital for an indeterminate period. In heroin overdose cases, pulmonary edema (as the result of altered capillary permeability) may occur. This is directly associated with the overdose and not with subsequent treatment. Aside from severe overdose, the drug causes or contributes to a number of ailments. These include chronic renal (kidney) failure and nephritic syndrome. Septic arthritis, caused by *Pseudomonas* and *Serratia* infections, is sometimes found as the result of

intravenous heroin abuse. Drug-induced immune platelet destruction also may occur.

Morphine. See separate entry on **Morphine**.

Neo-Synephrine®. See Phenylephrine hydrochloride later in this entry.

Nicotine, [CAS: 54-11-5] beta-pyridyl-alpha-N-methylpyrrolidine, $C_5H_4NC_4H_7NCH_3$, is a thick, water-white levorotatory oil that turns brown upon exposure to air. The compound is hygroscopic, soluble in alcohol, chloroform, ether, kerosene, water, and oils, bp 247 °C, at which point it decomposes. Specific gravity is 1.00924. Nicotine is combustible with an auto-ignition temperature of 243 °C. Nicotine is derived by distilling tobacco with milk of lime and extracting with ether. Nicotine is used in medicine, as an insecticide, and as a tanning agent. Nicotine is commercially available as the dihydrochloride, salicylate, sulfate, and bitartrate. Nicotinic acid (pyridine-3-carboxylic acid) is a vitamin in the B complex. See also **Vitamin**.

Phenylephrine Hydrochloride. [CAS: 61-76-7] *l*-1-(meta-hydroxyphenyl-2-methylaminoethanol hydrochloride, $HOC_6H_4CH(OH)CH_2NHCN_3{\cdot}HCl$, white or nearly white crystalline substance, odorless, bitter taste. Solutions are acid to litmus paper, freely soluble in water and in alcohol, mp 140–145 °C. Levorotatory in solution. Phenylephrine hydrochloride is used medically as a vasoconstrictor and pressor drug. It is chemically related to epinephrine and ephedrine. Actions are usually longer lasting than the latter two drugs. The action of phenylephrine hydrochloride contrasts sharply with epinephrine and ephedrine, in that its action on the heart is to slow the rate and to increase the stroke output, inducing no disturbance in the rhythm of the pulse. In therapeutic doses, it produces little if any stimulation of either the spinal cord or cerebrum. The drug is intended for the maintenance of an adequate level of blood pressure during spinal and inhalation anesthesia and for the treatment of vascular failure in shock, shock-like states, and drug-induced hypotension, or hypersensitivity. It is also used to overcome paroxysmal supraventricular tachycardia, to prolong spinal anesthesia, and as a vasoconstrictor in regional analgesia. Caution is required in the administration of phenylephrine hydrochloride to elderly persons, or to patients with hyperthyroidism, bradycardia, partial heart block, myocardial disease, or severe arteriosclerosis. The brand name *Neo-Synephrine®* is also used to designate another product (nose drops) which does not contain phenylephrine hydrochloride. The nose drops contain xylometazoline hydrochloride.

Quinine, [CAS: 130-95-0] $C_{20}H_{24}N_2O_2{\cdot}H_2O$, a bulky, white, amorphous powder or crystalline substance, with very bitter taste. It is odorless and levorotatory. Soluble in alcohol, ether, chloroform, carbon disulfide, oils, glycerol, and acids; very slightly soluble in water. Quinine is derived from finely ground cinchona bark mixed with lime. This mixture is extracted with hot, high-boiling paraffin oil. The solution is filtered, shaken with dilute sulfuric acid and then neutralized while hot with sodium carbonate. Upon cooling, quinine sulfate crystallizes out. Pure quinine is obtained by treating the sulfate with ammonia. In addition to medical uses, quinine and its salts are used in soft drinks and other beverages.

Quinine derivatives are used in therapy for mytonic dystrophy (usually weakness and wasting of facial muscles); in the treatment of certain renal (kidney) diseases. Quinine and derivatives are best known for their use in connection with malaria. Acute attacks of malaria are usually treated with oral chloroquine phosphate. The drug is given intramuscularly to patients who cannot tolerate oral medication. Combined therapy is indicated for treating *P. falciparum* infections, using quinine sulfate and pyrimethamine. A weekly oral dose of chloroquinone phosphate is frequently prescribed for persons who travel in malarial regions. The drug is taken one week prior to travel into such areas and continued for six weeks after leaving the region. Chloroquine phosphate has not proved fully satisfactory in the treatment of babesiosis, a malaria-like illness caused by a parasite.

Strychnine, [CAS: 52-24-9] $C_{21}H_{24}ON_2$, hard, white crystals or powder of a bitter taste. Soluble in chloroform, slightly soluble in alcohol and benzene, slightly soluble in water and ether, mp 268–290 °C, bp 270 °C (5 millimeters pressure). Strychnine is obtained by extraction of the seeds of *Nux vomica* with acetic acid, followed by filtration, precipitation by an alkali, followed by final filtration. The compound is highly toxic by ingestion and inhalation. The phosphate finds limited medical use. Strychnine is also used in rodent poisons. Strychnine acts as a powerful stimulant to the central nervous system. At one time, strychnine was used in a very carefully controlled way in the treatment of some cardiac disorders. Acute strychnine poisoning resembles fully developed generalized tetanus.

ALKALOSIS. A condition of excess alkalinity (or depletion of acid) in the body, in which the acid-base balance of the body is upset. The hydrogen ion concentration of the blood drops below the normal level, increasing the pH value of the blood above the normal 7.4. The condition can result from the ingestion or formation in the body of an excess of alkali, or of loss of acid. Common causes of alkalosis include: (1) overbreathing (hyperventilation), where a person may breathe too deeply for too long a period, consequently washing out carbon dioxide from the blood, (2) ingestion of excessive alkali, as for example an overdosage of sodium bicarbonate possibly taken for the relief of gastric distress, and (3) excessive vomiting, which leads to loss of chloride and retention of sodium ions. The usual, mild symptoms of alkalosis are restlessness, possible numbness or tingling of the extremities (hands and feet), and generally increased muscular irritability. Only in extreme cases, tetany (muscle spasm) and convulsions may be evidenced.

ALKANE. One of the group of hydrocarbons of the paraffin series with general formula CnH_{2n+2} where n is an integer, e.g., methane, ethane, and propane. See also **Organic Chemistry**.

Alkanes contain only saturated bonds and are relatively unreactive in the atmosphere, where they react by hydrogen abstraction to form alkyl radicals. Major sources include natural gas emissions, biomass burning, evaporative emissions, and fuel combustion.

ALKENE. One of a group of hydrocarbons having one double bond and the type formula C_nH_{2n}, where *n* is an integer, e. g., ethylene and propylene. Also called *olefins*. See also **Organic Chemistry**.

Alkenes are emitted in large quantities by automobiles and by vegetation. They react moderately to very rapidly with hydroxyl radicals and with ozone, which makes them major contributors to atmospheric reactivity, but limits their concentrations in the atmosphere. More complex dialkenes, with more than one double bond, can also be formed. See also **Ozone**.

ALKYD PAINTS. See **Paint and Finish Removers**.

ALKYD RESINS. In spite of challenges from many new coating resins developed over the years, alkyd resins as a family have maintained a prominent position for two principal reasons, their high versatility and low cost.

The main reactions involved in alkyd resin synthesis are polycondensation by esterification and ester interchange. There is usually some residual acidity as well as free hydroxyl groups left in the resin molecules.

Classification of Alkyd Resins

Alkyd resins are usually referred to by a brief description based on certain classification schemes. From the classification the general properties of the resin become immediately apparent. Classification is based on the nature of the fatty acid and oil length.

The oil length of an alkyd resin has profound effects on the properties of the resin.

For each of the three principal components of alkyd resins, the polybasic acids, the polyols, and the monobasic acids, there is a large variety to be chosen from. The selection of each of these ingredients affects the properties of the resin and may affect the choice of manufacturing processes. Thus, to both the resin manufacturers and the users, the selection of the proper ingredients is a significant decision.

The principal polybasic acids used in alkyd preparation include phthalic anhydride (mol wt 148, eq wt 74), isophthalic acid (mol wt 166, eq wt 83), maleic anhydride (mol wt 98, eq wt 49), fumaric acid (mol wt 116, eq wt 58), adipic acid (mol wt 146, eq wt 73), azelaic acid (mol wt 160, eq wt 80), sebacic acid (mol wt 174, eq wt 87), chlorendic anhydride (mol wt 371, eq wt 185.5), and trimellitic anhydride (mol wt 192, eq wt 64).

The principal types of polyol used in alkyd synthesis are shown are pentaerythritol (mol wt 136, eq 34) glycerol (mol wt 92, eq wt 31) trimethylolpropane (mol wt 134, eq wt 44.7) trimethylolethane (mol wt 120, eq wt 40) Ethylene glycol (mol wt 62, eq wt 31) Neopentyl glycol (mol wt 104, eq wt 52).

The overwhelming majority of monobasic acids used in alkyd resins are long-chain fatty acids of natural occurrence. They may be used in the form of oil or free fatty acid. Free fatty acids are usually available and classified by their origin, *viz*, soya fatty acids, linseed fatty acids, coconut fatty acids, etc. Fats and oils commonly used in alkyd resins include castor oil, coconut oil, cottonseed oil, linseed oil, oiticica oil, peanut oil, rapeseed oil, safflower oil, soyabean oil, sunflowerseed oil, and tung oil.

The drying property of fats and oils is related to their degree of unsaturation, and hence, to iodine values.

Linolenic acid is responsible for the high yellowing tendency of alkyds based on linseed oil fatty acids. Alkyds made with nondrying oils or their fatty acids have excellent color and gloss stability. They are frequently the choice for white industrial baking enamels and lacquers.

The behavior of alkyd resin reactions often deviates from that predicted by the theory of Flory. To explain this, a mechanism of microgel formation by some of the alkyd molecules at relatively early stage of the reaction was proposed. The microgel particles are dispersed and stabilized by smaller molecules in the remaining reaction mixture. As polyesterification proceeds, more microgel particles are formed, until finally a point is reached where they can no longer be kept separated. The microgel particles then coalese or flocculate, phase inversion occurs, and the entire reaction mass gels. The drying capability of an alkyd resin comes primarily from the microgel fraction. For example, when the highest molecular weight fraction representing about 20% of the total was removed through fractionation, a residual linoleic alkyd lost all ability to air dry to a hard film.

The process of alkyd resin designing should begin with the question "What are the intended applications of the resin?" The application dictates property requirements, such as solubility, viscosity, drying characteristics, compatibility, film hardness, film flexibility, acid value water resistance, chemical resistance, and environmental endurance With the targets in mind, a selection of oil length and a preliminary list of alternative choices of ingredients can then be made. For commercial production, the raw material list is screened based considerations of material cost, availability, yield, impact on processing cost, and potential hazard to health, safety, and the environmen. The list may be further narrowed by limitations imposed by the production equipment or other considerations. Once the oil length and ingredients are chosen, the first draft of a detailed formulation for the resin can be made.

A simple molecular approach is favored by some alkyd chemists for deriving a starting formulation. The basic premise of this approach is that when the total number of moles of the polyols is equal to or slightly larger than that of the dibasic acids, and the hydroxyl groups are present in an empirically prescribed excess amount, the probability of gelation is very small.

Different chemical procedures may be used for the synthesis of alkyd resins. The choice is usually dictated by the selection of the starting ingredients. Procedures include the alcoholysis process, the fatty acid process, the fatty acid–oil process, and the acidolysis process.

Depending on the requirements of the chemical procedures, the processing method may be varied with different mechanical arrangements to remove the by-product, water, in order to drive the esterification reaction toward completion. Methods include the fusion process and the solvent process.

The progress of the alkyd reaction is usually monitored by periodic determinations of the acid number and the solution viscosity of samples taken from the reactor. The frequency of sampling is commonly every half-hour.

The manufacturing of alkyd resins involves a wide variety of organic ingredients. Whereas most of them are relatively mild and of low toxicity, some, such as phthalic anhydride, maleic anhydride, solvents, and many of the vinyl (especially acrylic) monomers, are known irritants or skin sensitizers and are poisonous to humans. The hazard potential of the chemicals should be determined by consulting the Material Safety Data Sheets provided by the suppliers, and recommended safety precautions in handling the materials should be practiced.

With the ever-increasing awareness of the need of environment protection, the emission of solvent vapors and organic fumes into the atmosphere should be prevented by treating the exhaust through a proper scrubber. The solvent used for cleaning the reactor is usually consumed as part of the thinning solvent. Aqueous effluent should be properly treated before discharge.

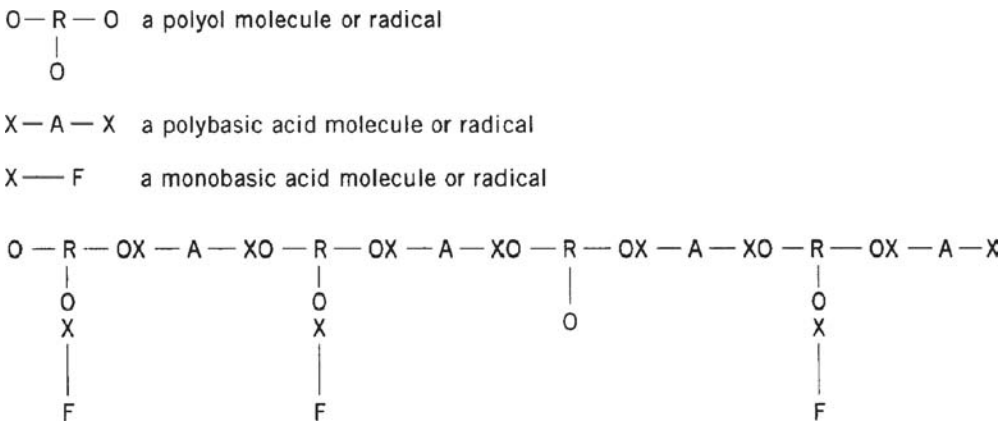

Fig. 1. Schematic representation of an alkyd resin molecule.

Modification of Alkyd Resins

One of the important attributes of alkyds is their good compatibility with a wide variety of other coating polymers. This good compatibility comes from the relatively low molecular weight of the alkyds, and the fact that the resin structure contains, on the one hand, a relatively polar and aromatic backbone, and, on the other hand, many aliphatic side chains with low polarity. An alkyd resin in a blend with another coating polymer may serve as a modifier for the other film-former, or it may be the principal film-former and the other polymer may serve as the modifier for the alkyd to enhance certain properties. Examples of compatible blends include: *Nitrocellulose*-based lacquers; *amino resins*; *Chlorinated rubber*; *vinyl resins*; *synthetic latex house paints*; and *silicone resins*.

Although blending with other coating resins provides a variety of ways to improve the performance of alkyds, or of the other resins, chemically combining the desired modifier into the alkyd structure eliminates compatibility problems and gives a more uniform product. Several such chemical modifications of the alkyd resins have gained commercial importance. They include vinylated alkyds, silicone alkyds, urethane alkyds, phenolic alkyds, and polyamide alkyds.

There has been a strong trend in recent years to increase the solids content of all coating materials, including alkyds, to reduce solvent vapor emission. In order to raise solids and still maintain a manageable viscosity, the molecular weight of the resin must be reduced. Consequently, film integrity must be developed through further chain extension or cross-linking of the resin molecules during the "drying" step. A high cross-linking density necessitated by the lower molecular weight of the resin builds high stress in the film and causes it to be prone to cracking. Therefore, adequate flexibility should be designed into the resin structure. Chain extension and cross-linking of high solids alkyd resins are typically achieved by the use of polyisocyanato oligomers or amino resins.

Replacing solvent-borne coatings with water-borne coatings not only reduces solvent vapor emission, but also improves the safety against the fire and health hazards of organic solvents. Alkyd resins may be made water-reducible either by converting the resin into an emulsion form or by incorporating "water-soluble" groups in the molecules.

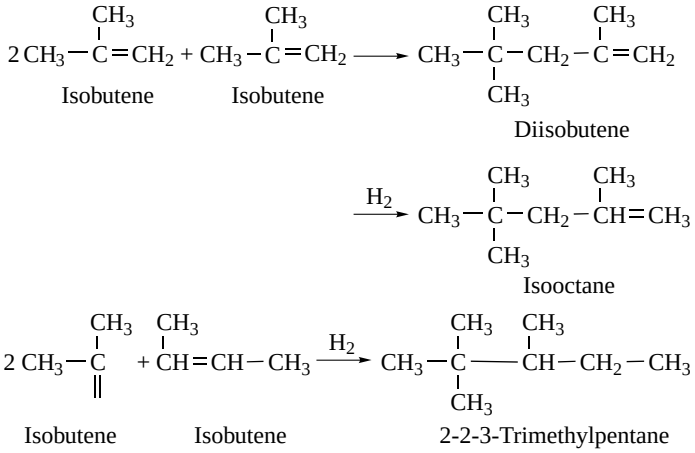
ALKYL. A generic name for any organic group or radical formed from a hydrocarbon by elimination of one atom of hydrogen and so producing a univalent unit. The term is usually restricted to those radicals derived from the aliphatic hydrocarbons, those owing their origin to the aromatic compounds being termed "aryl."

ALKYLATING AGENTS. See **Cancer and Oncology**.

ALKYLATION. Addition of an alkyl group. These reactions are important throughout synthetic organic chemistry; for example, in the production of gasoline with high antiknock ratings for automobiles or for use in aircraft.

The nature of the products of these reactions, as well as the yields, depend upon the catalysts and physical conditions. The reactions in Equation 1 have been written to show two combination reactions of two isobutene molecules, one yielding diisobutene, which reduces to isooctane, and the other yielding a trimethylpentane by a direct reduction reaction.



Specifically, the term is applied to various methods, including both thermal and catalytic processes, for bringing about the union of paraffin hydrocarbons with olefins. The process is especially effective in yielding gasoline of high octane number and low boiling range (aviation fuels).

In the petroleum industry, catalytic cracking units provide the major source of olefinic fuels for alkylation. A feedstock from a catalytic cracking units is typified by a C_3/C_4 charge with an approximate composition of: propane, 12.7%; propylene, 23.6%; isobutane, 25.0%; *n*-butane, 6.9%; isobutylene, 8.8%; 1-butylene, 6.9%; and 2-butylene, 16.1%. The butylenes will produce alkylates with octane numbers approximately three units higher than those from propylene.

One possible arrangement for a hydrofluoric acid alkylation unit is shown schematically in Fig. 1. Feedstocks are pretreated, mainly to remove sulfur compounds. The hydrocarbons and acid are intimately contacted in the reactor to form an emulsion, within which the reaction occurs. The reaction is exothermic and temperature must be controlled by cooling water. After reaction, the emulsion is allowed to separate in a settler, the hydrocarbon phase rising to the top. The acid phase is recycled. Hydrocarbons from the settler pass to a fractionator which produces an overhead stream rich in isobutane. The isobutane is recycled to the reactor. The alkylate is the bottom product of the fractionater (isostripper). If the olefin feed contains propylene and propane, some of the isostripper overhead goes to a depropanizer where propane is separated as an overhead product. A hydrofluoric acid (HF) stripper is required to recover the acid so that it may be recycled to the reactor. HF alkylation is conducted at temperature in the range of 24–38 °C (75–100 °F).

Sulfuric acid alkylation also is used. In addition to the type of acid catalyst used, the processes differ in the way of producing the emulsion, increasing the interfacial surface for the reaction. There also are important differences in the manner in which the heat of reaction is removed. Often,

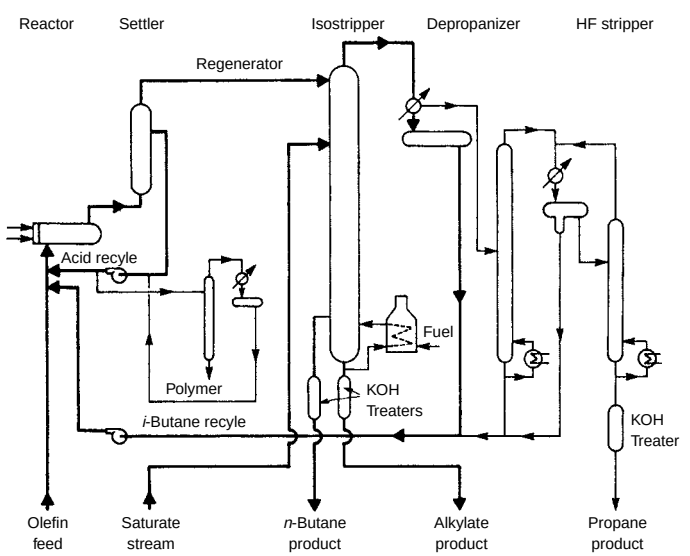


Fig. 1. Hydrofluoric acid alkylation unit. (*UOP Process Division.*)

a refrigerated cascade reactor is used. In other designs, a portion of the reactor effluent is vaporized by pressure reduction to provide cooling for the reactor.

ALKYNES. A series of unsaturated hydrocarbons having the general formula C_nH_{2n-2}, and containing a triple bond between two carbon atoms. The simplest compound of this series is acetylene [CAS: 74-86-2], HCC≡H. Formerly, the series was named after this compound, namely the *acetylene* series. The latter term remains in popular usage. Particularly, the older names of specific compounds, such as acetylene, allylene [CAS: 74-99-7], CH2CC≡H and crotonylene [CAS: 503-17-3], $CH_3CC{\equiv}CH_3$, persist. These compounds also are sometimes called *acetylenic hydrocarbons*. In the alkyne system of naming, the "yl" termination of the alcohol radical corresponding to the carbon content of the alkyne is changed to "yne." Thus, C_2H_2 (acetylene by the former system) becomes *ethyne*(the "eth" from ethyl (C_2); and C_4H_6 (crotonylene by the former system) becomes *butyne* (the "but" from butyl (C_4)). See also **Organic Chemistry**.

Alkynes are emitted to the atmosphere mainly as a result of incomplete combustion.

ALLANITE. Allanite is a rather rare monoclinic mineral of somewhat variable but quite complex chemical composition, perhaps represented satisfactorily by the formula $(Ce, Ca, Y)_2$ $(Al, Fe)_3Si_3O_{12}$ (OH). The color of the fresh mineral is black but it is usually brown or yellow with a coating of some alteration product; often the altered crystals have the appearance of small rusty nails. It occurs characteristically in plutonic rocks like granite, syenite or diorite and is found in large masses in pegmatites. Localities in the United States are in New York, New Jersey, Virginia, and Texas. The slender prismatic crystals are sometimes called orthite. Allanite was named for its discoverer, T. Allan. Orthite was so named from the Greek word meaning straight, in reference to the straight prisms, a common habit of this mineral.

ALLANTOIS. A sac-like outgrowth of the hind gut of the embryo found only in reptiles, birds and mammals. In reptiles and birds it serves as a respiratory organ and receives waste matter, and in mammals it forms part of the placenta through which all interchange with the blood of the mother during embryonic development is carried out.

ALLARD'S LAW. An equation used in predicting the night visual range of self-luminous targets.

Assume a light source at distance x from an observer and having (monochromatic) luminous power P_v in that person's direction. Then for uniform extinction coefficient σ, the illuminance E_v reaching the observer is

$$E_v = P_v x^{-2} \exp(-\sigma x)$$

When E_v equals the threshold illuminance for a given background luminance and detection probability, x is the night visual range, or maximum distance for detecting the light source.

ALLEGHENY OROGENY. The term for an event that caused deformation of the rocks of both the Valley and Ridge provinces, and of the adjacent Allegheny Plateau in the central and southern Appalachians. It is believed that most of the orogeny occurred late in the Paleozoic, but some phases may have extended into the early Triassic. Use of this term is preferred to the more inclusive term, Appalachian Revolution.

ALLELE. Also termed *allelomorph*, one of two or more forms of a gene that occupies a particular locus on a chromosome. In humans there is a gene at a particular locus on a chromosome that produces an enzyme essential to the breakdown of the amino acid phenylalanine. Since there are two of each kind of chromosome in a cell, a person will normally have two genes at this locus, one on each of the two chromosomes. If at least one of these genes is the allele for enzyme production, the person will be normal. If both genes are the allele for lack of enzyme production, the phenylalanine will not be broken down and the person will suffer from phenylketonuria (PKU). Hence, we say that the gene for enzyme production is the dominant allele and the gene for no enzyme is the recessive allele.

In many cases more than two alleles are known for a particular locus on a chromosome. These are called *multiple alleles*. One locus on the X-chromosome of the fruit fly, *Drosophila*, includes a number of alleles that can cause the eye to range in color from white to a deep red. The gene for red (wild type) eye is dominant over the other alleles, but there is some intermediate inheritance when two of the other alleles are present. An individual normally will carry no more than two alleles of a series.

ANN C. DEBALDO, College of Public Health,
University of South Florida, Tampa, FL

ALLELOPATHIC SUBSTANCE. A material contained within a plant that tends to suppress the growth of other plant species. The alkaloids present in several seed-bearing plants are believed to play an allelopathic role. Other suspected allelopathic substances contained in some plants include phenolic acids, flavonoids, terpenoid substances, steroids, and organic cyanides.

ALLERGENS. Allergens are a special type of (otherwise harmless) antigens that elicit allergic reactions in sensitized individuals. Classically, allergens have to gain access to the body, via either the skin (a tight lipophilic barrier) or a mucosal membrane (a less tight hydrophilic barrier). These two different modes of entry explain the differences in physicochemical properties of the allergens, as well as the differences in immune mechanism involved. In addition to these two most common modes of entry, some allergens bypass these barriers, either because of injection (stings, bites, drugs) or because of endogenous production (autoallergens or allergens produced by invading parasites). See also **Allergy**.

In all types of allergy, an asymptomatic phase precedes the symptomatic phase. During the asymptomatic phase sensitization develops as the immune system expands its potential to react to the allergen. It is thus often stated that allergy can be distinguished from nonallergic sensitivity by this gradual development of symptomatic reactivity. While a steady increase in exposure-related symptoms clearly supports the immunological/allergic nature of the process, the reverse is not necessarily true. Allergic reactions upon "first" contact do occur, particularly in food allergy (e.g. chicken egg white or peanut allergy in infancy). Hidden exposure (e.g. via the placenta or breast milk) or exposure to cross-reactive allergens are the most likely explanations for the development of allergy. See also **Hypersensitivity: Anaphylactic (Type I)**.

Allergen exposure subsequent to the sensitization phase will result in symptoms, but the severity of the symptoms within a single patient is often strikingly variable. Apart from obvious factors, such as the intensity of the exposure, there prove to be modulating factors ('nonspecific hyperreactivity', the constriction of the lung in response to irritation) that accompany allergen-specific hyperreactivity. A well-known example is the increase in the severity of asthmatic symptoms upon allergen exposure following some viral infections. An important complication often found following allergen exposure is a marked increase in nonspecific hyperreactivity. The inflammatory response induced by the allergen-specific reactions causes a local increase in the susceptibility to irritants. See also **Asthma**.

This article is limited to the three most important types of allergen: small nonproteinaceous lipophilic allergens penetrating the body via the skin (contact allergens), larger water-soluble proteinaceous allergens penetrating via the mucosa (inhaled and dietary allergens), and (glyco)proteins in hymenoptera venom.

Contact Allergens that Activate T Cells

Contact sensitivity is typically an immunological response to small reactive chemicals. Chemicals become antigenic only if they have the ability to bind to a protein. Such a reactive substance is then called a *hapten*. In some cases, chemicals are pro-haptens and acquire protein-binding capacity after modulation. For instance, poison ivy becomes allergenic after oxidation of one of its active components, 3-n-pentadecylcatechol, into a quinone. Photoallergic reactions may be induced or enhanced after the modification of a compound by ultraviolet light. The target proteins of haptens may be soluble or cell surface-bound. After protein binding, a new antigenic determinant arises, which can be recognized by T cells as foreign antigen. Frequent protein targets are class I and class II major histocompatibility complex (MHC) molecules expressed by antigen-presenting cells, especially the regions recognized by the T-cell receptor, such as the MHC groove loaded with antigen-derived peptide. In this way, contact sensitizers do not require intracellular processing,

as do protein allergens. As class I MHC proteins are recognized by CD8+ T cells and class II MHC proteins by CD4+ T cells, contact allergens activate both these T-cell subsets. Animal models indicate that in the elicitation phase of contact allergy the CD8+ T cells are more effective, probably due to their strong inflammatory phenotype. Alternatively, chemicals may first bind soluble protein. Such haptenized proteins become immunogenic only after they have been picked up by antigen-presenting cells, processed, and the haptenized peptide presented by (class II) MHC molecules.

Sensitization via skin occurs when the chemical is able to penetrate the corneal layer of the epidermis and bind to dendritic cells, the professional antigen-presenting cells for T helper (T_H) cells. A local irritation reaction is required to activate these dendritic cells to leave the skin and to migrate to the draining lymph nodes where they induce the clonal expansion of naive T cells specific to the haptenized protein antigen. Therefore, most contact sensitizers are (weak) irritants inducing the local production of various (pro)-inflammatory mediators in various immune and nonimmune cell types, allowing for effective activation of dendritic cells. After secondary skin contact, the local inflammatory reaction will evoke a rapid infiltration of expanded secondary hapten-specific T cells, which will aggravate the inflammatory reaction to a symptomatical level.

Testing and Prediction of Contact Allergens

Sensitization to contact allergens, the allergic state, is tested by the allergen skin patch test, which involves the epicutaneous application of the chemical under occlusion for 24–48 h. Patch test allergens are listed in the protocols of the international contact dermatitis research group. The contact allergenicity potential of compounds is difficult to predict. There are methods of prediction based on their physicochemical characteristics. The relative alkylation index (RAI) is a mathematical model based on the assumption that the degree of sensitization is closely correlated to the extent to which skin proteins become haptenated. The method of the qualitative and quantitative structure activity relationship is based on: (1) the reactivity of the chemical; (2) the ability of the chemical to penetrate the epidermis; and (3) the dose applied. Current biological tests are the guinea-pig maximalization assay, the mouse ear swelling test, and the local lymph node assay. Animal replacing models are under development.

Chemical Allergens: Structure

The number of compounds that can act as contact allergens is almost unlimited. However, there is a wide range of frequencies, varying from 5–10% of a given population to a single case. The frequency of allergy to a particular compound may vary considerably because of the variation of exposure. Most obvious examples are cases of plant-derived allergens. Poison ivy, a most frequent source of allergy in North America, does not grow in many other parts of the world.

Categories of allergens of low to moderate risk are:

- antimicrobial agents
- hairdressing products
- local anesthetics
- metals
- organic dyes
- organic mercury chemicals
- pesticides
- photographic chemicals
- plastics and glues
- rubber chemicals
- sunscreen agents

High-risk chemical compounds are:

- salts of heavy metals (e.g. nickel, chromium, cobalt, palladium and gold)
- formaldehyde and other aldehydes
- *p*-phenylenediamine
- balsam of Peru
- antibiotics (neomycin, penicillin)

Immunoglobulin E-dependent Allergens

Major and Minor Allergens. Most allergenic source materials contain many potentially allergenic molecules. Some are indisputably more important than others, but an exact definition of what should be called a *major* allergen rather than a *minor* allergen proves to be difficult. The commonly used definition is based upon prevalence of recognition of a particular substance by immunoglobulin E (IgE) from patients; for example, as more than 50% of patients with mite allergy have IgE antibodies to the group 1 allergens, group 1 allergens are considered to be major allergens. However, the prevalence is highly dependent on the selection of the patients: if only highly mite-sensitive patients are considered, the number of *major* allergens is clearly much higher than when only marginally sensitive patients are considered. Another definition is based on the effect of removing a single component from an allergen extract; if this does not have a measurable effect on the allergenic potency, this component is not considered a major allergen. This semantic discussion is not completely trivial, because the smaller the number of really important allergens, the sooner we will have a complete set of well-defined analytical and therapeutic reagents. As with any branch of science, allergology depends greatly on such defined reagents.

The "Atopy" Concept. IgE-inducing antigens are often referred to as "atopic" allergens. There is no universally accepted definition of atopy, but a genetic predisposition to develop IgE antibodies to allergens from pollen and mites is part of any definition. Some go much further and use the terminology "atopic allergen" for any substance that induces IgE antibodies; according to this view, anyone with IgE antibodies to any antigen will be an atopic subject. In this view, "atopic" is synonymous to "IgE antibody mediated." However, some antigens induce IgE antibodies in virtually anyone, independent of the genetic background. Classical examples are antigens from some tropical parasites (such as schistosomes) or from castor beans. Accordingly, a more restricted view of atopy holds that it reflects a constitutional predisposition to develop IgE antibodies to antigens that do not usually induce IgE antibodies in the general population. This leaves a grey area of antigens such as rodent urinary proteins (particularly following occupational exposure), hymenoptera venom proteins, and even regular vaccines, such as tetanus and diphtheria toxoids: these antigens may often induce IgE antibodies in the absence of an obvious family or personal history of atopy. See also **Allergy**; and **Asthma**.

Pathogenesis of Atopic Allergy: Allergens Activate B and T Helper Cells. In atopic allergic hypersensitivity reactions, various immune cells are activated according to mechanisms that are common to any antigen. In the sensitization phase, antigen is taken up by antigen-presenting dendritic cells residing in peripheral tissues (in case of inhalation allergens, the mucosal epithelium). These cells carry the allergen via lymphatics to T and B cells accumulated in the tissue-draining lymphoid organs. To activate B cells, antigen-presenting cells simply present native protein to the antigen receptor of B cells. Within a single allergen extract, B cells recognize various proteins, and each protein can be recognized in various ways. This means that the allergen-specific repertoire of B cells is diverse.

To activate T cells, antigen-presenting cells have to process antigen and expose antigen-derived peptides in the pockets of MHC molecules on their cell surface, as T cells have antigen receptors that recognize antigen-derived peptides only in the context of MHC. The route of processing and presentation of exogenous proteins, such as allergens, implies the expression of peptides associated with class II MHC molecules, which are recognized primarily by T_H cells that express CD4 molecules on their cell surface. As for B cells, the allergen-specific repertoire of T cells is diverse as they recognize peptides derived from different proteins in an allergen extract, whereas each protein renders various antigenic peptides.

Pathogenesis of Atopic Allergy: Aberrant Signals from T Helper Cells to B Cells. After activation, B cells produce immunoglobulins directed against antigen. However, the level of production and the immunoglobulin type strongly depends on the type of support of immunoregulatory T_H cells. The support by T_H cells requires intimate interaction by B and T_H cells with the same antigen specificity, and is mediated by soluble (cytokines) as well as membrane-bound molecules. Immunoglobulin production by B cells is predominantly determined by the level and types of cytokines produced by the antigen-specific T_H cells. There is strong evidence that allergen sensitization in atopic patients results in the activity of T_H cells (T_H2) that produce high levels of the type 2 cytokines interleukin (IL) 4, IL-5 and IL-13 in response to protein antigens. IL-4 and IL-13 support the production of IgE by B cells, whereas IL-5 supports the maturation and activation of eosinophils. In contrast, allergen-specific T cells in nonallergic subjects produce balanced levels of type 1 and type 2 cytokines, leading to low levels of IgE and eosinophils. Thus far, the reason for the

cytokine imbalance in allergen-specific T cells of atopic allergic subjects is unknown.

Inhaled Allergens. To inhale a nonvolatile allergen, the allergen has to become airborne by virtue of the aerodynamic properties of the particle to which it is attached. Droplets from steaming foods have been reported to induce allergic reactions, but by far the most common mode of exposure is via dry, "dusty" (i.e. slowly settling) particles such as pollen grains, skin flakes, small fibers and organic debris. It is not the particle itself, but rather macromolecules leaching off the particle upon impact with the aqueous phase of the airway mucosa, that is responsible for the allergic reaction. The dissolved allergen then has to cross the membrane, first to trigger the immune system and later to trigger the effector system: IgE bound to its receptor on mast cells and presumably also IgE bound to its receptor on antigen-presenting cells that may activate inflammatory T cells. Allergens are usually released rapidly in aqueous solution. Their molecular mass is mostly in the 10–50-kDa range. Most airborne allergens have to survive in an environment where they are exposed to oxygen and sunlight; accordingly, they are usually rugged macromolecules. The actual exposure level of an individual to airborne allergen per year is very low (in the low microgram range). Only in selected situations, such as occupational exposure or exposure to indoor furred pets, will the annual exposure be in excess of 1 mg. This is very different from the exposure to food proteins, where exposure may easily be more than a million times higher.

Plant Allergens. Pollen from wind-pollinating plants is both abundant and slowly sedimenting, so among the airborne antigens it is understandably important. The relative importance of the three major sources (grasses, trees and weeds) is obviously very much dependent on the geographical area. Some of the well-defined allergens are the group 1 allergens from trees (e.g. Bet v 1 from birch tree, 17 kDa, belongs to a family of pathogenesis-related proteins; its cross-reactivity with homologous proteins in apples and other fresh fruits is responsible for some food-allergic reactions), the group 1 and 5 allergens from grasses (e.g. Lol p 1 from Rye grass, 26 kDa, function unknown, and Dac g 5 from orchard grass, 27 kDa, related to ribonucleases) and ragweed allergen Amb a 1 (40 kDa, pectate lyase). See also **Pollen: Structure, Development and Function**.

A minor pollen allergen (profilin, 14 kDa, involved in actin polymerization) is important primarily because of its cross-reactivity with homologous proteins in many vegetable foods.

Molds and Fungi. Molds and fungi are relatively poorly characterized. Alt a 1 from *Alternaria alternata* is a 14-kDa protein of unknown function. Asp f 1 is a 17-kDa protein from *Aspergillus fumigatus* belonging to the ribonuclease family.

Invertebrates: Mites and Insects. Indoor mites, particularly from *Dermatophagoides pteronyssinus*, *D. farinae* and *Euroglyphus maynei*, are among the most important allergen-producing organisms. It is still hotly debated whether these allergens are in any way special to account for this allergenicity. In particular, the allergological relevance of the proteolytic activity of the group 1 allergens (25 kDa, cysteine protease) is being investigated. However, the group 2 allergens (14 kDa) are equally allergenic and yet do not have (known) enzymatic activity; they are related to proteins involved in molting of invertebrates. Some other mite allergens are also known to be proteases, but are allergologically less important (group 3, 6 and 9 allergens). Group 10 allergen of mites is a muscle protein, tropomyosin. Its main relevance in relation to allergy is its cross-reactivity and heat stability; it is a major allergen from shrimp and presumably other foods of invertebrate origin. See also **Mite (Arachnida, Acarina)**.

Insects may also cause allergy, not only via stings and bites, but also via inhalation of insect debris. Cockroach is the most extensively studied species. One of the allergens of the German cockroach, Bla g 2, is a 36-kDa aspartate protease. Bla g 4 is a 20-kDa protein belonging to the family of lipocalins; many of the mammalian allergens also belong to this family (see below). See also **Insect**.

Vertebrate Allergens. Some vertebrate allergens (e.g. from bovine milk and chicken egg) are primarily food related; these are discussed below. Vertebrate allergens become airborne only if they are secreted or excreted by the animal. Urine, saliva and secretions from various skin glands are the most important sources. These secretions contain some plasma proteins, such as serum albumin, but these are usually not the most relevant allergens. Secretions of most, if not all, animals contain ligand-binding proteins, either to bind signal molecules from the environment (e.g. smell or taste perception) or to transport pheromones to the outside world. One very prominent class of ligand-binding protein is the lipocalin family, small proteins of 17–24 kDa with a distinct protein fold. Lipocalins have been found to be important allergens in the case of dog, horse, cow, rodents and even in invertebrates (e.g. cockroach; see above). Despite the similarity in protein folding, the homology in the amino acid sequence is often low (less than 50%) and, therefore immunological cross-reactivity is not as marked as with some plant proteins (e.g. profilins; see below). The cat is remarkable in producing a group of closely related proteins in different secretions that do not appear as prominently in other species. This allergen is called Fel d 1. It is a four-chain 45-kDa glycoprotein consisting of a short chain 1 and a longer chain 2, two of each. Chain 1 is homologous to another group of ligand-binding proteins (completely unrelated to the lipocalins), produced by the Clara cell in the airways and by cells in the uterus. No homologues of chain 2 have yet been described. Fel d 1 is produced both in salivary glands and by skin glands, and its production is to some extent regulated by sex hormones.

Dietary Allergens. Dietary allergens may act at two different levels: in either the (peri)oral region or the intestinal region. Allergic reactions in the (peri)oral region are usually due to cross-reactivity with pollen allergens; this cross-reactivity is discussed below. True food allergens are relatively resistant to the common food processing steps: cooking and digestion by gastric juice. The most important true food allergens in the Western world are chicken egg white, cow's milk, peanut, fish and shrimp.

Natural Rubber Latex Allergy. Latex allergy is a complicated issue, both because of the complex nature of the source material and because of the distinctive modes of contact. It is important to note that "latex allergy' is a misleading terminology: latex is used for material derived from different raw materials, whereas the allergic reactions are confined to latex derived from natural rubber (i.e. *Hevea brasiliensis*). Exposure to allergens from natural rubber may occur via skin contact (which may result in T cell-mediated contact sensitivity or IgE-mediated allergy), via parenteral routes (surgical procedures, particularly in patients with spina bifida), or via inhalation of dust from powdered gloves (e.g. in the hospital environment). Gloves, condoms and balloons are common products that are often made of rubber latex which may induce allergic reactions. See also **Latex**.

Some of the proteins in rubber latex cross-react with some vegetable foods, particularly banana and avocado. It is not always clear whether the food or the latex is the primary sensitizer. The accurate prediction of the severity of allergic symptoms in subjects with demonstrable IgE antibodies is not yet possible. This is unfortunate, because the prevalence of such antibodies is high and, whereas some subjects with such IgE antibodies may develop a severe, or even fatal, allergic reaction upon parenteral latex exposure during operation, the majority will not. A better definition of the important allergens might improve the diagnostic accuracy. Most importantly, of course, the content of soluble protein components in natural rubber latex should be kept as low as possible. Changes in the manufacturing process have already resulted in a marked decrease in allergenicity.

Hymenoptera Venoms. Hymenoptera venoms are relatively well studied because of their widespread use in the treatment of patients with generalized reactions following an insect sting. Phospholipase A_2 (17 kDa) from bee venom is an important allergen, but hyaluronidase might be even more important. The mechanism of the generalized reaction that is occasionally observed following a sting (and which may be fatal) is incompletely known. IgE antibodies are likely to contribute, but are not particularly good predictors of outcome, so other factors are clearly also important. The protective effects of venom injections (i.e. venom immunotherapy) may depend partly on antitoxic immunity, as well as on antiallergic mechanisms. See also **Hypersensitivity: Anaphylactic (Type I)**; and **Venoms**.

Cross-reactivity between Inhaled and Dietary Allergens. Some food substances induce allergic symptoms, but do not themselves sensitize (e.g. the apple allergen that cross-reacts with the major birch pollen allergen Bet v 1). The apple protein is usually not responsible for the induction of IgE antibodies: the lymphoid cells of the immune system never "see" the apple allergen, but the IgE antibodies are induced by a cross-reacting allergen. In this example, birch pollen grains in the nose release Bet v 1 molecules, which induce in an immune response, including IgE antibodies, to many epitopes on this molecule. Most of these antibodies are specific for the birch protein, but some are cross-reactive, for example with the homologous protein from apple. These IgE antibodies circulate through

the body and will fix to mast cells in the oral area. Upon subsequent oral contact with apple proteins, the local mast cells will react, inducing perioral symptoms. Another vegetable protein in this category is profilin, for which pollen from grasses, trees, as well as weeds, is a relatively common sensitizer, and raw vegetables (e.g. carrots) are good elicitors.

The reverse situation also occurs: a food protein inducing immunological sensitivity, which may subsequently result in symptoms following inhalation of a cross-reacting allergen. One example is sensitization to shrimp proteins, which induces allergic airway reactions upon the inhalation of mite allergens.

Most of the above-mentioned examples of cross-reactivity are due to evolutionarily conserved proteins. Sugar chains on glycoproteins are a different type of structure that may cause cross-reactivity. This is particularly true for nonmammalian glycans, such as vegetable or invertebrate glycans. This type of cross-reactivity is distinct in several ways. Most importantly, the symptoms caused by this type of cross-reactivity seem usually to be less severe. Furthermore, cross-reactivity may be found over evolutionarily wide distances, for example between insects, mollusks and grass pollen. Finally, these structures are chemically more stable than most proteins, so they survive procedures that will destroy most proteins.

ALLERGY. A reaction to a specific substance in an individual who is sensitive to that substance. If the material is borne by the wind and produces symptoms of allergy when it comes into contact with the mucous membranes of the eyes and respiratory tract, the victim is said to have *hay fever*. There are two main types: (1) *seasonal hay fever* is the most common and occurs during the spring and summer seasons as the result of pollen from various trees, grasses, and weeds (the most common cause); and (2) *non-seasonal or perennial hay fever*, that may be caused by allergic reactions to house pets, foods, dust, and numerous other substances. In most cases, the causative substance is inhaled.

It is believed that, in part, the reason some people react to various allergens while others do not is due to hereditary factors. A primary factor is thought to be the predisposition of allergic individuals to produce inappropriately high levels of *IgE* to potential allergens. Hay fever is not inherited, but the tendency to develop an allergic disease may be inherited. Other contributing factors include psychic stress, infections, and endocrine disturbances. Any of these factors may trigger an attack. It should be stressed that the term *hay fever* is a misnomer, in that the condition is not ordinarily associated with hay or a fever. The term was used by an English physician (Bostock), himself a victim, in a report in 1812. His symptoms occurred during the haying season.

Nearly all cases of seasonal hay fever are caused by pollen. The pollen from many sweet-scented flowers is disseminated by insects, but that causing hay fever is usually spread by the wind. Since many plants produce large quantities of pollen, a sensitive person can easily become overexposed and experience an immediate reaction. Seasonal hay fever can be caused by three different groups of plants, each of which has a somewhat different season. Trees produce pollen that causes hay fever during the months of April and May in the Northern Hemisphere (October and November in the Southern Hemisphere). Various grasses are responsible for much of the hay fever that occurs during the first half of May to the first part of July (first half of November to first part of January in Southern Hemisphere). From the middle of August to October (middle of February to April in Southern Hemisphere), weeds are active pollen producers.

Usually, the least severe and least common form of seasonal hay fever is that which is induced by pollen from trees. It is estimated that 10% of all seasonal hay fever is caused by tree pollen. The oak tree is the most common tree causing hay fever and is found widely in the United States. Three other offenders, the cottonwood, the cedar, and the poplar, grow profusely in the southern and southwestern regions of the United States. Other trees with allergy-producing pollen include the birch, alder, hickory, black walnut, beech, maple, hackberry, sycamore, mulberry, and elm.

Grasses appear to account for about 35% of all cases of seasonal hay fever. The three most common grasses involved are Timothy, Bermuda, and June (blue grass). There are eighty varieties of grasses found in various sections of the United States that have a common antigen. Therefore, a person sensitive to one type of grass is usually sensitive to all types of grasses.

Weeds are prolific pollen producers, some varieties producing more than 100,000 pollen grains from a single plant. The most causative agents include various species of ragweed and the thistle. Other weeds involved, but not on a wide scale, include goosefoot, buckwheat, marsh elder, rabbit bush, cocklebur, hemp, and pigweed.

Non-seasonal hay fever may be caused by the hair, feathers, or dander of a household or farm pet. Some individuals are sensitive to feathers in pillows or to kapok, the fibers used as filling for mattresses. House dust, especially in the bedroom, is a common causative agent. Workers in mills where wheat or corn is ground often inhale the flour-like powder, which produces irritation of the nasal mucous membranes. Reproductive cells of some fungi, when inhaled, may stimulate an allergic response.

Non-seasonal hay fever may be caused by certain foods, in particular eggs, chocolate, milk, coffee, or shellfish. Aspirin and quinine may be causative agents. Non-seasonal hay fever may be continuous or spasmodic, depending upon the length of contact with the exciting factor. The symptoms of non-seasonal hay fever tend to be less severe than symptoms of the seasonal variety. At their mildest, they may consist of slight nasal congestion with sniffing, a tendency to an itchy nose, postnasal drip, and mouth breathing.

While the symptoms of hay fever are not difficult to recognize, the actual type of hay fever is not so easily determined. The prior history of a patient is of prime importance. Were there allergic reactions during childhood? Family history is helpful to determine any disposition toward the disease. In particular, details concerning the patient's living habits and possible exposure to various causative agents are important.

Skin tests (also known as "scratch" tests or immediate hypersensitivity tests) are frequently made to obtain needed information. A series of small intradermal injections of suspected allergens are made in the skin and the area is examined 30 minutes later. If the test is positive, a large, red, itching wheal will appear. If no reaction occurs after half an hour, the material is removed and the reaction is regarded as negative. The tests are not infallible. Some individuals have more sensitive skin than others. Consequently, false positive reactions are not uncommon. A second type of test, used less frequently, is an eye test. A drop of solution of pollen extract is dropped into the eye. If the reaction is positive, a condition similar to the eye symptoms of hay fever results.

In lieu of living in areas where the pollen count is low (often difficult for a variety of employment, economic, family and other reasons), air conditioning of the home or office is helpful. A variety of drugs provide

relief of hay fever symptoms. Antihistamines are often used and help a high percentage of individuals. Ephedrine-like drugs, taken at night and either alone or in combination, are effective in lessening early morning symptoms. Corticosteroids are useful in severe cases where other agents are not effective.

Preventive treatment also is available. It is designed to acclimate a person's body to the irritant, once identified. The treatment is commenced approximately three months prior to the usual onset of an attack, known from past history of the patient. The treatment consists of the injection of the pollen extract at intervals of about a week. The dosage is gradually increased until the largest dose is given at about the time the symptoms usually start. From then on, the dosage remains the same until the end of the season. At the beginning of treatment, there may be a mild reaction on the spot where the injection was given. Subsequent dosage is regulated by the severity of this reaction. The pollen extract treatment has been beneficial in many cases.

The treatment of patients with non-seasonal hay fever consists of completely avoiding the substance or substances which cause the attack. Should contact be absolutely necessary, the physician may prescribe the allergen extract treatment, particularly if the patient's symptoms are so severe as to incapacitate him in his work.

In some allergic conditions there may be upsets of the digestive system, and occasionally severe headaches may result. In all of these cases, there may be some accompanying change in the skin, but in other commonly encountered allergies, the skin changes constitute about the only symptoms. The specific skin symptom may bear very little relation to the cause of the allergy; a particular antigen produces varying types of responses in the skin of different individuals.

One of the most common skin changes associated with allergy is simply a reddening (*erythema* or *hyperemia*), caused by increased amounts of blood in the lower layers of the skin due to localized capillary dilatation. Reddened areas of this type may be restricted to a small area of the body, or may be general over its surface. They turn white when subjected to pressure from a finger, seldom are long-lasting, and either disappear within a few days, or progress into some other type of symptom.

Hives (*urticaria*) is a common skin condition in which whitish or reddish, slightly elevated areas of the skin appear. These wheals may be small, like pimples (*papules*), or much larger patches or streaks (*welts*). They generally cover the entire body, being most common on areas covered by clothing. Hives are caused by the accumulation of tissue fluids (*edema*) beneath the epidermis in areas seen as wheals. The condition generally arises rapidly, may last for an hour or so, and then disappears as quickly as it came, if its cause has been removed. See also **Urticaria**.

Another symptom frequently associated with allergy is known as *eczema*. There is a reddening of the skin, followed by the appearance of minute blisters or *vesicles*. These vesicles become larger and are generally accompanied by intense itching. In acute cases, these blisters break and exude a fluid that forms a crust on the skin. The crust then flakes off, frequently as the result of a secondary inflammation of the skin. Eczema may cover any area of the body, and is one of the most severe of all allergic symptoms. Eczema-type reactions of the skin may result also from some infections and as the result of various nervous conditions.

Other symptoms occasionally seen as the result of an allergy include *nodules*, which are small hard bodies beneath the skin, and large blisters (*blebs* or *bullae*). As the result of the various skin changes which occur, secondary lesions eventually may develop. These include abrasions or erosions, fissures or cracks, ulcers, and scars. These secondary lesions are seldom encountered when the patient receives prompt treatment and the cause of the allergy is determined and removed.

Food allergies in infants frequently result in a severe eczema, and are most often caused by egg white, milk, wheat, oats, barley, and corn. Since eczema may result the first time an infant eats egg white or some other of these foods, it seems possible that sensitization of a child may have occurred while it was receiving its nourishment through the placenta before birth. Infantile eczema most often appears in the second or third month of life and may disappear spontaneously by the end of the second year, with no remaining signs of the food hypersensitivity. The condition may appear again or become worse following vaccination, colds, or eruption of the teeth. Sensitivity to egg, wheat, and milk usually occurs less frequently with increasing age, and disappears almost completely between the fourth and twelfth years.

A large number of chemical substances when taken into the body or applied to the body's surface are capable of producing severe allergic symptoms. Not only are such skin conditions encountered as the result of some medicine to which the body has become sensitized, but they also occur as the result of contact with various industrial chemicals.

Skin eruptions caused by drugs differ somewhat from other allergies, in that they frequently manifest brighter colors, appear suddenly, occur symmetrically on the body, are frequently extensive, and do not generally produce any other body disturbances. Most symptoms disappear after administration of the drug is stopped. Skin eruptions caused by iodides and bromides disappear more slowly and those caused by arsenic hypersensitivity may appear long after the drug has been taken and may last indefinitely. Hypersensitivity to phenolphthalein (used in some laxatives) also may produce an inflammation that lasts long after administration of the drug has been stopped.

Among the more common drugs that may cause eruptions might be listed acetanilide, amidopyrine, antipyrine, arsenic compounds, aspirin, atabrine, barbituric acid derivatives, benzoic acid, benzocaine, opium and morphine, penicillin, phenobarbital, phenolphthalein, quinine, salicylic acid, sulfonamides, and turpentine. Except for reactions to penicillin, it is evident that, when one considers the number of persons to whom they are administered without ill effects, allergy to any one of these drugs is a relatively rare condition. Included among the various medicinal preparations which are capable of producing allergies should be mentioned the various sera and other animal products. When various immunizing sera, such as tetanus antitoxin, are repeatedly injected into an individual, they occasionally produce a sensitive condition as the result of the development of antibodies against the proteins in the serum. In some acute cases, the entire body may react violently to a further administration of the same serum. The dangerous condition, which occurs within a few moments in such cases, is known as *anaphylactic shock*. Modern methods of preparing the sera for injection have caused a marked decrease in the incidence of this condition.

Workers sometimes develop a hypersensitivity to materials to which they are constantly exposed, as bakers to flour, barbers to quinine (hair tonics), dentists to Novocaine, painters to linseed oil, and so on. Various soaps and detergents are also common allergens, although these agents are more often responsible for *primary irritant dermatitis*, a condition easily confused with true allergy. Toilet preparations, cosmetics, clothing, and a host of other substances can set up an allergic reaction in some people. Insect bite hypersensitivity is common. In some individuals, a simple mosquito bite may produce a large and painful swelling out of all proportion to that seen in most other persons. Bites or stings by bees, wasps, bedbugs, lice, fleas, gnats, caterpillars, and various marine fishes and other animals may produce extreme reactions in some few individuals who have previously been sensitized to the allergenic materials of the particular species.

Heat, cold, and light may be the direct cause of burn, chapping, and sunburn, but in some sensitive persons, they may produce allergic skin changes. These usually take the form of hives. In most cases, the symptoms subside rapidly after the cause has been removed.

Mental and emotionally induced allergic symptoms also may appear. The mechanism is not well understood, but it is believed that strong emotions may release various chemical substances into the bloodstream, substances which are capable of sensitizing the body and which act as allergens.

ALLIGATION. A simple mathematical method for calculating the correct proportioning of the ingredients of a mixture or, in general, the value of a property of a mixture from the values of that property in its components. It is based upon the formula

$$P_{xy} = \frac{xX + yY}{x + y}$$

in which P_{xy} is the value of a property of the mixture, X and Y are its values in the components, and x and y are the proportions of the components. It assumes, of course, no change in properties on mixing.

ALLIGATOR. See **Crocodiles and Alligators**.

ALLIUM *(Liliaceae)*. A large genus whose species are found widely. Some 75 species are found in North America, especially in the western states. All are bulbous plants with flat or tubular leaves, and with spherical heads or umbels of variously colored flowers. Particularly important cultivated species are the onion, *Allium cepa*; leek, *Allium porrum*; garlic, *Allium sativum*; and chives, *Allium schoenoprasum*. One European species now extensively introduced in the United States is the common weed, field garlic, *Allium vineale*, which (if eaten by cows) noticeably flavors milk and butter.

ALLOBAR. A form of an element differing in atomic weight from the naturally occurring form, hence a form of element differing in isotopic composition from the naturally occurring form.

ALLOCHROMATIC. With reference to a mineral that, in its purest state, is colorless, but that may have color due to submicroscopic inclusions, or to the presence of a closely related element that has become part of the chemical structure of the mineral. With reference to a crystal that may have photoelectric properties due to microscopic particles occurring in the crystal, either present naturally, or as the result of radiation.

ALLOCHROMY. Any fluorescence, or reradiation of light, in which the wavelength (and hence color) of the emitted light differs from that of the absorbed light.

ALLOCHTHONOUS. A term proposed by Gümbel in 1888 for sedimentary rocks whose constituents have been transported and deposited at some distance from their place of origin. The bulk of the sedimentary rocks are of this type. The term is now used most commonly in reference to masses of rock transported considerable distances by tectonic movements. See **Overthrust**.

ALLOGENIC (Ecology). Successive ecological events or conditions that result from factors which arise from outside the natural community and thus alter the more localized situation. The term may be applied, for example, to an allogenic drought of very long duration.

ALLOGENIC (Geology). Minerals and rock constituents derived from preexisting rocks that have been transported from their original site. The term also applies to a stream (allogenic stream) which is fed by water from a distant terrain. An example would be a stream that originates in a humid or glacial region and later flows through an arid or desert region.

ALLOGYRIC BIREFRINGENCE. A beam of plane-polarized light may be regarded as the resultant of two equal beams of circularly polarized light, one right-handed and the other left-handed. The phenomenon of optical rotation may be represented by assuming that in optically active media, circularly polarized light is transmitted unchanged, but the velocity of left-handed circularly polarized light is not the same as that of right-handed circularly polarized light. Fresnel demonstrated this difference directly, and the phenomenon is called allogyric birefringence.

ALLOMERISM. A property of substances that differ in chemical composition but have the same crystalline form.

ALLOMORPHISM. A property of substances that differ in crystalline form but have the same chemical composition.

ALLOTROPES. See **Chemical Elements**.

ALLOTYPE. An animal or plant fossil selected, as a species or subspecies, as illustrating morphological details not shown in the holotype.

ALLOYS. Traditionally, an alloy has been defined as a substance having metallic properties and being composed of two or more chemical elements of which at least one is a metal (ASM). Although this still covers the general use of the word, in recent years alloy also has been used in connection with other, non-metallic, materials. Most metals are soluble in one another in their liquid state. Thus alloying procedures usually involve melting. However, alloying by treatment in the solid state without melting can be accomplished in some instances by such methods as powder metallurgy. When molten alloys solidify, they may remain soluble in one another, or may separate into intimate mechanical mixtures of the pure constituent metals. More often, there is partial solubility in the solid state and the structure consists of a mixture of the saturated solid solutions. Another important type of solid phase is the inter-metallic compound, which is characterized by hardness and brittleness and usually has only limited solid solubility with the other phases present. The interactions of two or more elements both in the liquid and solid state are effectively characterized by phase diagrams. Where only two principal materials are involved, *binary alloy* is the term used. Three principal ingredients are referred to as *ternary alloy*. Beyond three components, the material may be referred to as a multi-composition system or alloy.

The decade of the 1980s witnessed the development of hundreds of new alloys, involving not only the traditional metals, but much greater use of the less common chemical elements, such as indium, hafnium, etc. In this encyclopedia, alloys of a chemical element are discussed mainly under that particular element, or in an entry immediately following. Also check alphabetical index.

In addition to the appearance of numerous new alloys, sometimes called superalloys, recent developments in this field include many relatively new processes and methodologies, such as electron beam refining, rapid solidification, single-crystal superalloys, and metallic glasses, among others. Some of these are described in separate articles in this encyclopedia.

Motivation for the development of new alloys is found in nearly all consuming areas, but particular emphasis has been given to the expanding and increasingly demanding requirements of the aircraft and aerospace industries, including much attention directed to the lighter elements (titanium, aluminum, etc.); the needs of the military; the very difficult requirements of jet engine parts; and the electronics industry where much attention has been directed toward the less common metals. Within recent years, metallurgists also have come to appreciate that processing of alloys can be of as much importance as the elements they contain. New processes have been developed during the past decade or so, including rapid solidification, electron beam refining, and many others. Metal alloy research also has been impacted by the rapidly and continuously expanding science and art of making composites, often involving ceramics, graphite, organics, etc. in addition to metals. Knowledge of alloys not only must assist the applications of simply the alloys themselves, but also how the alloys perform in a composite part.

Predicting the Performance of Alloys. It is well known that many important alloy combinations have properties that are not easy to predict, simply on the basis of knowledge of the constituent metals. For example, copper and nickel, both having good electrical conductivity, form solid-solution type alloys having very low conductivity, or high resistivity, making them useful as electrical resistance wires. In some cases very small amounts of an alloying element produce remarkable changes in properties, as in steel containing less than 1% carbon with the balance principally

iron. Steels and the age-hardening alloys depend on heat treatment to develop special properties such as great strength and hardness. Other properties which can be developed to a much higher degree in alloys than in pure metals include corrosion-resistance, oxidation-resistance at elevated temperatures, abrasion- or wear-resistance, good bearing characteristics, creep strength at elevated temperatures, and impact toughness. However, solid state physics has been successful in explaining many of these properties of metal and alloys.

There are various types of alloys. Thus, the atoms of one metal may be able to replace the atoms of the other on its lattice sites, forming a substitutional alloy, or solid solution. If the sizes of the atoms, and their preferred structures, are similar, such a system may form a continuous series of solutions; otherwise, the miscibility may be limited. Solid solutions, at certain definite atomic proportions, are capable of undergoing an order-disorder transition into a state where the atoms of one metal are not distributed at random through the lattice sites of the other, but form a superlattice. Again, in certain alloy systems, inter-metallic compounds may occur, with certain highly complicated lattice structures, forming distinct crystal phases. It is also possible for light, small atoms to fit into the interstitial positions in a lattice of a heavy metal, forming an interstitial compound.

In this encyclopedia alloys of chemical elements of alloying importance are discussed under that particular element.

Alloy Phase Diagram Data Programme

Alloy phase diagrams have been known since 1829 when the Swedish scientist Rydberg, who observed the thermal effects that occur during the cooling of binary and ternary alloys from a molten condition. Gibbs many years later published a treatise on the theory of heterogeneous equilibria. The practical importance of phase diagrams awaited the development of the phase diagram for the iron-carbon system, which became central to the metallurgy of steel. See **Iron Metals, Alloys, and Steels**. With the development over the years of scores of binary alloys, considering the number of chemical elements involved, and then followed by ternary and much more complex alloys — with many hundreds of professionals in the metal sciences contributing knowledge — the problems of collecting and of easily locating such information took on formidable proportions. The start of an effective database was the publication of a compilation, by Hansen in 1936, of information gleaned from the literature on 828 binary systems, for which sufficient data were available to construct phase diagrams for 456 binary systems. An English version of the German works, updated to some extent, appeared in 1958. This compilation included 1324 binary systems and 717 binary phase diagrams. A supplementary volume by R.P. Elliott brought the number of binary phase diagrams to 2067 and a later work by F.A. Skunk (1969) included data on 2380 systems. These efforts became key reference works for metallurgists concerned with alloy development and alloy applications. For obvious reasons, information on ternary phase diagrams and other multicomponent systems was far less satisfactory.

To improve this important metallurgical database, the National Bureau of Standards (U.S.) and the American Society for Metals, after many prior deliberations, each signed a memorandum of agreement to proceed with a data programme for alloy phase diagrams, concentrating on binary systems. As early as 1975, T.B. Massalski (Carnegie-Mellon University), then chairman of the programme, observed that a knowledge of phase diagram data is basic for the technological application of metals and alloys; that any programme to provide critically evaluated data would have to be a worldwide enterprise because there is too much work for any institution or organization, or even any country, to accomplish the task alone; that the programme should deal with binary and multicomponent systems; that a computerized bibliographic database should be developed; that computer technology should be used to provide data for the generation of phase diagrams at remote terminals; and that funding for the programme should be sought. As of the late 1980s, many of these objectives had been achieved. Among organizations not previously mentioned, cooperation has been given by the Institute of Metals (U.K.), the U.K. Universities' Science Research Council, the Max-Planck Institut für Metallforschung (Stuttgart), among several other sources, including funding from various interested corporations.

The massive task required that data be sorted into categories by some thirty editors. The first comprehensive publication to be released thus far is from the American Society for Metals (ASM International), entitled "Binary Alloy Phase Diagrams," which contains up-to-date and comprehensive phase diagram information for more than 1850 alloy systems, representing the first major release of critically evaluated phase diagrams since 1969.

Importance of Phase Diagrams. As pointed out by Massalski and Prince (1986), phase diagrams are graphic displays of the thermodynamic relationships of one or more elements at different temperatures and pressures. It has been stated that phase diagrams are to the metallurgist what anatomy is to the medical profession or cartography to the explorer. To explain this analogy, reference is made to a specific phase diagram (Fig. 1). This gold-silicon (Au-Si) phase diagram is a two-dimensional mapping of the phases that form between Au and Si as a function of temperature and of alloy composition. In Fig. 1(a), the alloy composition is defined in terms of the percentage of atoms of Si in the alloy. It will be noted that a dramatic lowering of the freezing point of pure gold (1064.43 °C) occurs upon the addition of silicon. Conversely, there is a more regular depression of the freezing point of Si (1414 °C) upon the addition of Au.

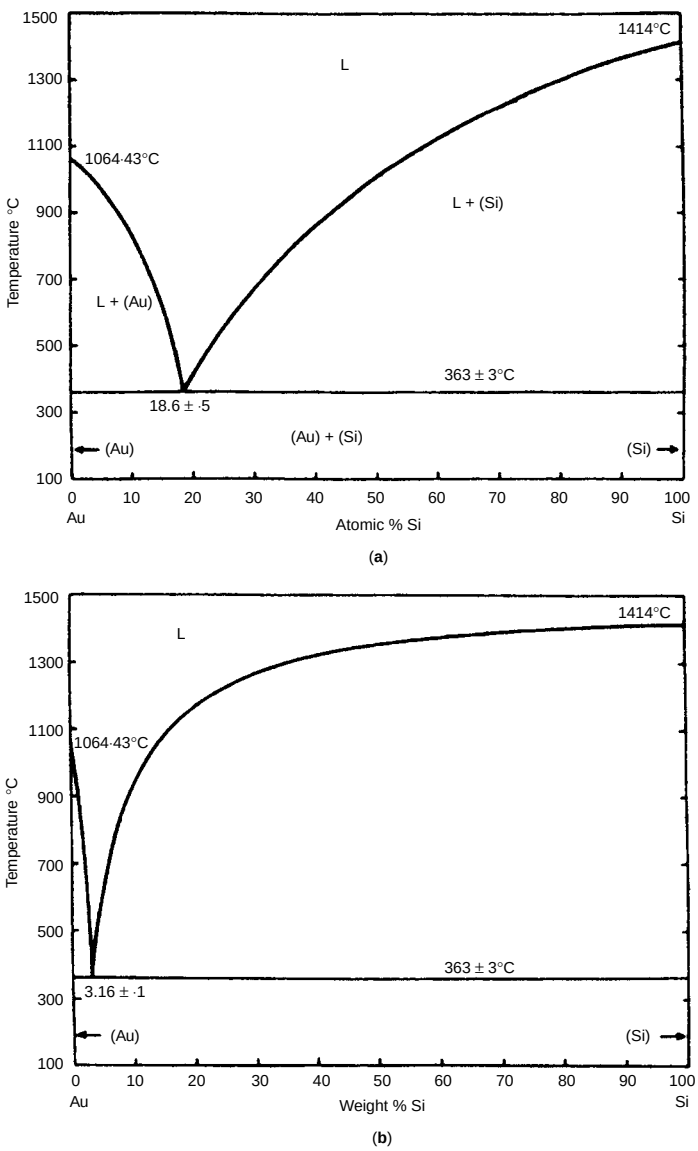

Fig. 1. Representative binary alloy phase diagrams: **(a)** the Au-Si phase diagram with compositions in atomic percent; **(b)** the Au-Si phase diagram with compositions in weight percent. (*ASM News*.)

The two upper curves, termed the *liquidus curve*, define the temperatures at which Au-Si alloys begin to solidify. The curves meet at 363 °C at an alloy composition containing 18.6 atomic percent Si. At this temperature, all Au-Si alloys, irrespective of composition, complete their solidification

by the eutectic separation of a fine mixture of Au and Si from the liquid phase containing 18.5 atomic percent Si. The horizontal line at 363 °C is called the *solidus* because below such a line all of the alloys are completely solid.

The effect of presenting the alloy composition in terms of the weight percentage of Si is shown in Fig. 1(b). The liquidus curves drop even more dramatically towards the Au-rich side of the phase diagram and the eutectic liquid at 363 °C contains only 3.16 weight percent Si. The movement of the eutectic composition, the lowest-melting alloy composition, from 18.6 percent Si of Fig. 1(a) to 3.15 weight percent Si in Fig. 1(b) simply reflects the great difference in the atomic weights of Au and Si.

Massalski and Prince selected this particular phase diagram because of its simplicity for illustration and because this particular phase diagram is of considerable importance in the semiconductor device industry. Silicon chips are frequently bonded to a heat sink, using a gold alloy or more frequently a Au-Si alloy foil placed between them. Upon heating above 363 °C, the Au reacts with Si to form a brazed joint between the silicon chip and the heat sink.

Phase diagrams are condensed presentations of a large amount of information. They provide quantitative information on the phases present under given conditions of alloy composition and temperature and, to the experienced metallurgist, a guide to the distribution of the phases in the microstructure of the alloy. They also dictate what alterations in phase constitution will occur with changing conditions, whether these be alteration of alloy composition, temperature, pressure or atmosphere in equilibrium with the material.

Further, the phases present in an alloy and their morphological distribution within the microstructure, define the mechanical, chemical, electrical, and magnetic properties that may be achievable. Thus, we have the essential link between the engineering properties of an alloy and its phase diagram. Indeed, a distinctive feature of metallurgy as a profession is that it is primarily concerned with the relationship between the constitution and the properties of alloys. Phase diagram data are key elements to understanding, and thereby controlling, the properties of alloys.

Broad Categories of Alloys

Although there are thousands of alloys, with many new alloys appearing each year, there are certain traditional alloys that serve the vast majority of materials needs. The bulk of new alloys, although extremely important, are frequently application-specific. The broad classes are described briefly as follows.

CAST FERROUS METALS

Gray, Ductile, and High-Alloy Irons

In gray iron, most of the contained carbon is in the form of graphite flakes, dispersed throughout the iron. In ductile iron, the major form of contained carbon is graphite spheres, which are visible as dots on a ground surface. In white iron, practically all contained carbon is combined with iron as iron carbide (cementite), a very hard material. In malleable iron, the carbon is present as graphite nodules. High-alloy irons usually contain an alloy content in excess of 3%.

Malleable Iron

The two main varieties of malleable iron are ferritic and pearlitic, the former more machinable and more ductile; the latter stronger and harder. Carbon in malleable iron ranges between 2.30 and 2.65%. Ranges of other constituents are: manganese, 0.30 to 0.40%; silicon, 1.00 to 1.50%; sulfur, 0.07 to 0.15%; and phosphorus, 0.05 to 0.12%.

Carbon and Low-Alloy Steels

Low-carbon cast steels have a carbon content less than 0.20%; medium-carbon steels, 0.20 to 0.50%; and high-carbon steels have in excess of 0.50% carbon. Ranges of other constituents are: manganese, 0.50 to 1.00%; silicon, 0.25 to 0.80%; sulfur, 0.060% maximum; and phosphorus, 0.050% maximum.

Low-alloy steels have a carbon content generally less than 0.40% and contain small amounts of other elements, depending upon the desired end-properties. Elements added include aluminum, boron, chromium, cobalt, copper, manganese, molybdenum, nickel, silicon, titanium, tungsten, and vanadium.

High-Alloy Steels

When "high-alloy" is used to describe steel castings, it generally means that the castings contain a minimum of 8% nickel and/or chromium. Commonly thought of as stainless steels, nevertheless *cast grades* should be specified by ACI (Alloy Casting Institute) designations and not by the designations that apply to similar *wrought alloys*.

WROUGHT FERROUS METALS

Carbon Steels

These steels account for over 90% of all steel production. There are numerous varieties, depending upon carbon content and method of production. In one classification, there are *killed* steels, *semikilled* steels, *rimmed* steels, and *capped* steels. These are described in considerable detail under **Iron Metals, Alloys, and Steels**.

High-Strength Low-Alloy Steels

There are several varieties, with high-yield strength depending mainly on the precipitation of martensitic structures from an austenitic field during quenching. Small additions of alloy elements, such as manganese and copper, are dissolved in a ferritic structure to obtain high strength and corrosion resistance.

Low and Medium-Alloy Steels

The two basic types are (1) *through* hardenable, and (2) *surface* hardenable. Subcategories of surface hardenable alloys include carburizing alloys, flame and induction-hardening alloys, and nitriding alloys.

Stainless Steels

A stainless steel is defined as iron-chromium alloy that contains at least 11.5% chromium. There are three major categories: (1) austenic, (2) ferritic, and (3) martensitic, depending upon the metallurgical structure. There are scores of varieties. Type 302 is the base alloy for austenitic stainless steels. Representative stainless steels in this category provide some insight into why so many varieties are made, and how rather small changes in composition and production can bring about significant differences in the final properties of the various stainless steels. A slightly lower carbon content improves weldability and inhibits carbide formation. An increase in nickel content lowers the work hardening. By increasing both chromium and nickel, better corrosion and scaling resistance is achieved. The addition of sulfur or selenium increases machinability. The addition of silicon increases scaling resistance at high temperature. Small amounts of molybdenum improve resistance to pitting corrosion and temperature strength.

High-Temperature, High-Strength, Iron-Base Alloys

There are two general objectives in making these alloys: (1) they can be strengthened by a martensitic type of transformation, and (2) they will remain austenitic regardless of heat treatment and derive their strength from cold working or precipitation hardening. Again, there are numerous types. Considering the main types, the carbon content may range from 0.05% to 1.10%; manganese, 0.20 to 1.75%; silicon, 0.20 to 0.90%; chromium, 1.00 to 20.75%; nickel, 0 to 44.30%; cobalt, 0 to 19.50%; molybdenum, 0 to 6.00%; vanadium, 0 to 1.9%; tungsten, 0 to 6.35%; copper, 0 to 3.30%; columbium (niobium), 0 to 1.15%; tantalum, 0 to <1%; aluminum, 0 to 1.17%; and titanium, 0 to 3%.

Ultrahigh-Strength Steels

Normally a steel is considered in this category if it has a yield strength of 160,000 psi or more. The first of these steels to be produced was a chromium-molybdenum alloy steel, shortly followed by a stronger chromium-nickel-molybdenum grade.

Free-Machining Steels

Normally, the carbon content is kept under 0.10%, but as much as 0.25% carbon has little deleterious effect on machinability. Aluminum and silicon are held to a minimum (aluminum not used as a de-oxidizer where machinability is extremely important). Lead, sulfur, bismuth, selenium, and tellurium (0.04%) improve machinability when in the proper combination. Sulfur improves machinability by combining with any manganese and oxygen present to form oxysulfides.

NONFERROUS METALS

Aluminum Alloys

These alloys are available as wrought or cast alloys. The principal metals alloyed with aluminum include copper, manganese, silicon, magnesium, and zinc. These alloys are discussed in considerable detail under **Aluminum Alloys.**

Copper Alloys

These alloys are available as wrought or cast alloys. The principal wrought copper alloys are the brasses, leaded brasses, phosphor bronzes, aluminum bronzes, silicon bronzes, beryllium coppers, cupro-nickels, and nickel silvers. The major cast copper alloys include the red and yellow brasses, manganese, tin, aluminum, and silicon bronzes, beryllium coppers, and nickel silvers. The chemical compositions range widely. For example, a leaded brass will contain 60% copper, 36 to 40% zinc, and lead up to 4%; a beryllium copper is nearly all copper, containing 2.1% beryllium, 0.5% cobalt, or nickel, or in another formulation, 0.65% beryllium, and 2.5% cobalt.

Nickel Alloys

Although nickel is present in varying amounts in stainless steel *commercially* a high-nickel stainless steel is not categorized as a nickel *alloy*, but rather as a stainless steel. Most nickel alloys are proprietary formulations and hence designated by trade names, such as *Duranickel*, *Monel* (several), *Hastelloy* (several), *Waspaloy*, *Rene 41*, *Inco*, *Inconel* (several), and *Illium* G. The nickel content will range from about 30% to nearly 95%.

Magnesium Alloys

It is the combination of low density and good mechanical strength which provides magnesium alloys with a high strength-to-weight ratio. Again, these generally are proprietary formulations. Aluminum, manganese, thorium, zinc, zirconium, and some of the rare-earth metals are alloyed with magnesium.

Zinc Alloys

Zinc alloys are available as die-casting alloys or wrought alloys. The principal alloys used for die casting contain low percentages of magnesium, from 3.5 to 4.3% aluminum, and carefully controlled amounts of iron, lead, cadmium, and tin.

Titanium Alloys

The titanium-base alloys are considerably stronger than aluminum alloys and superior to most alloy steels in several respects. Several types are available. Alloying metals include aluminum, vanadium, tin, copper, molybdenum, and chromium.

METALLIC GLASSES

Potentially, metallic glasses and metastable crystalline alloys are the strongest, toughest, and most corrosive resistant, and the most easily magnetizable materials known to materials engineers. Metallic glasses often are quite superior to their crystalline counterparts. This is an important reason why rapid solidification technology has attracted worldwide attention. Several factors are recognized as affecting an alloy's ability to form a metallic glass. These include atomic size ratio, alloy crystallization temperature and melting point, and heat of formation of compounds. In addition to drastic supercooling of a metal alloy, metallic glasses have been made by electro-deposition or by vapor deposition. These non-crystalline metal or alloy compounds are sometimes referred to as *amorphous* alloys.

ALLSPICE. Sometimes called *pimento*, allspice is prepared from the dried, pea-size, unripened, dark reddish-brown berry of a West Indian evergreen tree (*Pimenta officinalis* L.). The tree, which reaches a height of about 20 feet (6 meters) is an evergreen and a member of the Myriaecea (myrtle) family, of which probably the best known members are bayberry trees and shrubs.

The word *pimento* is not to be confused with the word *pimentio* (see **Pepper**). The substances are not related. Also, to contribute to word confusion, allspice is sometimes called Jamaica pepper, a term which tends to associate it with the more familiar black or white pepper of the family *Piperiaceae*. There is no such association.

Allspice is well named because its essence and taste resemble that of a mixture of cinnamon, nutmeg, and cloves. Pimento oil is a fragrant essential oil distilled from allspice berries. It contains eugenol and cineol,

which have a carnationlike essence. Allspice finds numerous uses in food products, including:

Bakery products — special breads and rolls; muffins; coffee cakes; spice cakes; fruit cakes; fruit, chocolate, and custard cream pies.
Beverages — cordials and liqueurs.
Condiments — catsup, chili sauce.
Confections — licorice.
Ethnic dishes — German foods.
Fruits and fruit-based products — apples; applesauce; apple drink; apricots; cranberry drink; cranberry sauce; peaches; pears; plums; preserves; spiced fruits; stewed fruits.
Meats and meat dishes — bologna; beef; frankfurters; hamburger; head cheese; meatloaf; mincemeat; pork; sausage.
Pickles.
Poultry.
Sauces — tomato sauce.
Soups — beef; consommé; tomato; vegetable.
Vegetables — beans, beets; cole slaw; spinach; squash; sweet potatoes; tomatoes; turnips.

ALLUVIAL FAN. Also called *subaerial delta*, a cone-shaped to delta-shaped collection of coarsely graded sediments deposited by intermittent streams that debouch from steep valleys onto a relatively gentle slope or plain. Alluvial fans may extend for many miles. Confluent fans may eventually cover and fill relatively large intermontane basins. An alluvial-fan shoreline is one in which an alluvial fan is built out into a lake or sea.

ALLUVIUM. A general term used to designate the sand, silt, and mud deposited by a stream, along its bank or upon its floodplain, during periods of high water. The word is derived from the Latin *ad*, to; and *luo*, wash. When alluvium is relatively fine-textured and contains sufficient organic matter it forms soil. Some of the oldest and richest agricultural regions are the great delta areas, such as the Nile and Euphrates.

ALLYL ALCOHOL AND MONOALLYL DERIVATIVES. The technology of introducing a new functional group to the double bond of allyl alcohol was developed in the mid-1980s. Allyl alcohol [CAS: 107-18-6] C_3H_6O, is accordingly used as an intermediate compound for synthesizing raw materials such as epichlorohydrin [CAS: 106-89-8] C_3H_5ClO and 1,4-butanediol [CAS: 110-63-4] $C_4H_{10}O_2$, and this development is bringing about expansion of the range of uses of allyl alcohol.

The term "allyl" of allyl compounds is derived from "allium," the Latin word for garlic. Garlic contains a colorless, odorless compound "alliin," which is a precursor for producing a characteristic garlic flavor. When a garlic bulb is cut or mashed, the cell tissue of garlic is broken and an enzyme "alliinase" contained in garlic is activated. In the presence of alliinase, alliin is converted to allicin, which is a very unstable compound and is quickly transformed to allyl sulfides such as diallyl disulfide. These compounds generate a characteristically pungent garlic odor and flavor. In contrast, when a garlic bulb is heated, alliinase is inactivated, inhibiting transformation of alliin to allicin. Thus, a pungent flavor is not generated.

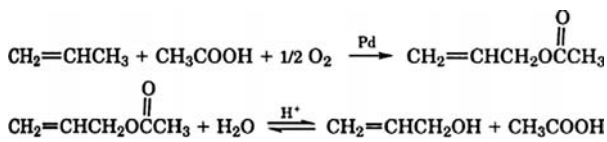
Allyl Alcohol

Allyl alcohol is a colorless liquid having a pungent odor; its vapor may cause severe irritation and injury to eyes, nose, throat, and lungs. It is also corrosive. Allyl alcohol is freely miscible with water and miscible with many polar organic solvents and aromatic hydrocarbons, but is not miscible with *n*-hexane. It forms an azeotropic mixture with water and a ternary azeotropic mixture with water and organic solvents. Allyl alcohol has both bacterial and fungicidal effects.

Boiling point of allyl alcohol is 96.90 °C, freezing point, −129 °C, density 0.8520, refractive index, 1.413, flash point, 25 °C. The C=C double bond of allyl alcohol undergoes addition reactions typical of olefinic double bonds. Hydroformylation of allyl alcohol is a synthetic route for producing 1,4-butanediol, a raw material for poly(butylene terephthalate), an engineering plastic. The substitution activity of the hydroxyl group of allyl alcohol is lower than that of the chloride group of allyl chloride and the acetate group of allyl acetate. However, allyl alcohol undergoes substitution reactions under conditions in which saturated alcohols do not react. Reactions proceed in catalytic systems in which a π-allyl complex is considered as an intermediate.

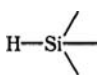
The C=C double bond of allyl alcohol undergoes epoxidation by peroxide, yielding glycidol. This epoxidation reaction is applied in manufacturing glycidol as an intermediate for industrial production of glycerol.

There are four processes for industrial production of allyl alcohol. One is alkaline hydrolysis of allyl chloride. A second process has two steps. The first step is oxidation of propylene to acrolein and the second step is reduction of acrolein to allyl alcohol by a hydrogen transfer reaction, using isopropyl alcohol. At present, neither of these two processes is being used industrially. Another process is isomerization of propylene oxide. Until 1984, all allyl alcohol manufacturers were using this process. Since 1985 Showa Denko K.K. has produced allyl alcohol industrially by a new process which they developed. This process, which was developed partly for the purpose of producing epichlorohydrin via allyl alcohol as the intermediate, has the potential to be the main process for production of allyl alcohol. The reaction scheme is as follows:



Monoallyl Derivatives

The addition reaction of silane



to the C=C double bond of allyl compounds is applied in the industrial synthesis of silane coupling agents.

Allyl halide, allyl ester, and other allyl compounds undergo oxidative addition reactions with low atomic valent metal complexes to form π-allyl complexes.

The physical properties of some important monoallyl compounds are summarized in Table 1.

Allyl Chloride. This derivative, abbreviated AC, is a transparent, mobile, and irritative liquid. It can be easily synthesized from allyl alcohol and hydrogen chloride. However, it is industrially produced by chlorination of propylene at high temperature.

Allyl chloride is industrially the most important allyl compound among all the allyl compounds. It is used mostly as an intermediate compound

TABLE 1. PROPERTIES OF IMPORTANT ALLYL COMPOUNDS

Property	Allyl chloride	Allyl acetate	Allyl methacrylate	AGE[a]	Allyl amine	DMAA[b]
Molecular formula	C_3H_5Cl	$C_5H_8O_2$	$C_7H_{10}O_2$	$C_6H_{10}O_2$	C_3H_7N	$C_5H_{11}N$
CAS Registry Number	[107-05-1]	[591-87-7]	[96-05-9]	[106-92-3]	[107-11-9]	[2155-94-4]
Molecular weight	76.53	100.12	126.16	114.14	57.10	85.15
Boiling point, °C	44.69	104	150	153.9	52.9	64.5

Flash point, °C	−31.7	6	33	57.2	−29	−23

[a] Allyl glycidyl ether.
[b] Dimethylallylamine.

for producing epichlorohydrin, which is consumed as a raw material for epoxy resins.

Allyl Esters. Allyl acetate is produced mostly for manufacturing allyl alcohol.

At present, allyl methacrylate, AMA, is used mostly as a raw material for silane coupling agents.

The C−H bond of the allyl position easily undergoes radical fission, especially in the case of allyl ethers, reacting with the oxygen in the air to form peroxide compounds.

Therefore, in order to keep allyl ether for a long time, it must be stored in an air-tight container under nitrogen.

Allyl glycidyl ether is used mainly as a raw material for silane coupling agents and epichlorohydrin rubber.

Allylamine can be synthesized by reaction of allyl chloride with ammonia at the comparatively high temperature of 50−100 °C, or at lower temperatures using $CuCl_2$ or CuCl as the catalyst.

Dimethylallylamine is used in the production of insecticides and pesticides.

Most allyl compounds are toxic and many are irritants. Those with a low boiling point are lachrymators. Precautions should be taken at all times to ensure safe handling.

Allyl compounds are harmful and may be fatal if inhaled, swallowed, or absorbed through skin. They are destructive to the tissues of the mucous membranes and upper respiratory tract, eyes, and skin.

ALMAGEST. The name assigned by the Arabs to the great treatise on science compiled by Ptolemy during the second century. The very name Almagest, which is a hybrid combination of the Greek superlative ($\mu \in \gamma \iota o \tau \eta$) with the Arabic article (al), indicates the importance of this work to the early astronomers.

The Almagest is a collection of treatises on a variety of scientific subjects. In it is to be found the complete exposition of the Ptolemaic system for the structure of the universe. Perhaps the best-known section of the Almagest is that dealing with the stars and the constellations. This section was taken from the works of Hipparchus and incorporated in the Almagest by Ptolemy, with some improvements and additions. It is in this catalogue that we first find the brightnesses of the stars divided into six magnitudes, a system that has persisted down to modern times. The positions of the stars given in the Almagest have proven of some little value in determining the constants of precession and, also, the proper motions of the stars.

ALMANAC (Astronomical). For the work of every person engaged in astronomy, whether as an astronomer in an observatory, as a navigator on a ship at sea or in the air, or as a surveyor in the field, tables of certain astronomical data are indispensable. Many, in fact most, of these tables change from year to year. Among such materials may be listed the positions of the sun, moon, and planets for every day in the year; accurate positions of stars to be used for determination of local time; tables for computing precession, nutation, aberration, etc. Such material is computed and published in almanacs several years in advance.

In addition to the ephemerides and data listed above, astronomical almanacs also contain descriptions of such phenomena as eclipses of the sun and moon, occultations of stars by the moon, eclipses and configurations of the satellites of Jupiter, etc. An examination of the preface for the American Ephemeris and Nautical Almanac or the publications in Great Britain of H.M. Stationery Office for any year will show how the work for that particular year was distributed.

ALMERIA-ORAN FRONT. See **Meteorology**.

ALMWIND. See **Winds and Air Movement**.

ALOE *(Liliaceae).* A large genus of plants characteristic of drier parts of Africa, especially the southern part. Because of their ornamental appearance, with stiff habit and spiny-margined leaves, many of them are grown in cultivation. The rather small yellow or red flowers are borne in large masses. Many species yield from the crushed leaves a purgative juice, which is called aloes, and which has been used extensively by eastern people.

ALONG-VALLEY WINDS. See **Winds and Air Movement**.

ALONG-VALLEY WIND SYSTEMS. See **Winds and Air Movement**

ALOPECIA (Hair Loss). Normally, this condition is confined to various portions of hair, but *alopecia universalis* designates the loss of all body hair. Alopecia is of two forms — scarring (*cicatricial*) or nonscarring (*noncicatricial*). In the scarring form, the follicles are destroyed, resulting in permanent hair loss.

Male Pattern Baldness (Androgenetic Alopecia). This condition mainly affects the vertex and frontal regions of the scalp in males. However, this form of alopecia may be seen in young women, infrequently, as the result of some underlying endocrine disease. Causes of androgenetic alopecia that have been suggested by some researchers include an excessive production of dihydrotestosterone (DHT) in the affected areas. It has been established that DHT is a potent androgenic end-organ effector in certain tissues. From time to time, cures for male baldness have been suggested. For example, there has been speculation that a specific pharmacological blocking agent (an antiandrogen) might be applied topically to block androgenetic alopecia. Experience with animals along these lines has been encouraging, but lasting success on humans requires considerably more proof.

Alopecia Areata. This condition, still of unknown etiology, appears to be associated with a variety of probably autoimmune diseases, including pernicious anemia, thyroiditis, and Addison's disease. Complete hair loss may develop on the scalp or other hair-bearing areas, such as beard or eyebrows. The areas usually are well circumscribed. Some tenderness may accompany the lesions. In the early stage, hairs exhibit a tapered shaft and clubbed bulb, sometimes termed "exclamation point" hairs. Complete baldness in the area then generally follows. Distribution of hair loss in a peripheral band around the scalp is called *ophiasis*. Where there is no underlying endocrine disease present, a spontaneous regrowth of hair may occur within a three-year period. Other persons exhibit a more chronic course. The complete loss of scalp hair is called *alopecia totalis*.

Treatment of alopecia areata takes the form of topical application or intralesional injection of high-potency corticosteroids, which experience indicates will promote regrowth of hair, but only so long as the therapy is continued. Good temporary responses in cases of extensive alopecia areata have been obtained from systemic corticosteroids.

Drug-Induced Alopecia. Thinning of hair may result from iron deficiency anemia, hypothyroidism, or hyperthyroidism. Cytotoxic agents, including antimetabolites, such as administered in cancer therapy, can cause *anagen effluvium* by interfering with mitotic activity in the hair follicles. Hair shafts become thin and break off easily. Upon cessation of the use of cytotoxic drugs, the hair loss is reversible. Other drugs which (usually after administration for over three months) cause diffuse hair loss include heparin, triparanol, thiourea, indomethacin, lithium carbonate, nitrofurantoin, propanolol, probenecid, allopurinol, and, sometimes, excessive intakes of vitamin A.

Alopecia also has been associated with the use of oral contraceptives, the condition resembling that of androgenetic alopecia in women, as previously mentioned.

Permanent hair loss may result from certain fungal and bacterial infections and from a number of underlying causes, such as discoid lupus erythematosus, scleroderma, folliculitis decalvans, among others, the description of which is beyond the scope of this encyclopedia.

Various "treatments" for alopecia, particularly for males, have been offered to the public for a century or more with little, if any, evidence of effectiveness or universal acceptance by the medical profession. Currently, at least one pharmaceutical manufacturer is offering a product publicly, but it is obtainable only by prescription in the United States. The best source of information is a patient's dermatologist.

ALPENGLOW. (German *Alpenglühen*, from *Alpen* Alps + *Glühen to* glow) The word "alpenglow" describes a visual phenomenon where the summits of snow-covered mountains cast a pinkish, magenta color during either sunrise or sunset. In mountainous areas such as the Alps, this can be caused by snow, moisture, and ice on mountain sides which receive the scattered red light from the setting Sun. This optical phenomenon is named after the Alps Mountains.

Alpenglow has three phases. During evening twilight, the first stage is the mountain peak's usual coloration seen at low sun elevations h_0 ($h_0 < 2^\circ$). Second is the alpenglow proper that occurs a few minutes after the first color has faded (h_0 slightly less than 0°). The peaks are still in direct sunlight, and their colors are purer and often pinker than before. The alpenglow boundary may first occur hundreds of meters below the summit, then moves upward, and finally fades as the atmosphere's dark segment rises. Third is the afterglow, which occurs nearly simultaneously with the first purple light. The peaks are no longer in direct sunlight; the illumination is more diffuse and its boundary vaguer than in the earlier stages. The third stage lasts longer than the other two ($-5^\circ < h_0 < -9^\circ$), and its color varies from yellow to purple. A faint second afterglow has been reported and is associated with the rare occurrence of a second purple light. The alpenglow appears to be much less common at sunrise than at sunset. The morning colors are more pink and purple, while those of evening are more orange and red.

ALPHA (α) (Chemistry). 1. A prefix denoting the position of substituting atom or group in an organic compound. The Greek letters α, β, γ, etc., are usually not identical with the IUPAC numbering system 1, 2, 3, etc., since they do not start from the same carbon atom. However, α and β are used with naphthalene ring compounds to show the 1 and 2 positions, respectively. α, β, etc., are also used to designate attachment to the side chain of a ring compound.

2. Both a symbol and a term used for relative volatility in distillation.

3. Symbol for optical rotation.

4. A form of radiation consisting of helium nuclei.

5. The major allotropic form of a substance, especially of metals, e.g., α-iron.

ALPHA CENTAURI. Ranking third in apparent brightness among the stars, Alpha Centauri has a true brightness value of 1.5 as compared with unity for the sun. Alpha Centauri is a yellow, spectral type G star and is one of the terminal stars in the pattern of the constellation Centaurus located south of the ecliptic. In the mid-1800s, the South African astronomer, Thomas Henderson, determined that Alpha Centauri is the nearest star to the sun, an estimated 4.3 light years distant. Actually, Alpha Centauri is a double star, with a third star, Proxima Centauri, revolving around the two stars. Alpha Centauri and another star in the constellation Centaurus, Beta Centauri, form a line which points quite closely to the south pole of the celestial sphere. See also **Constellations**; and **Star**.

ALPHA CHAMBER. A counter tube or counting chamber for the detection of alpha particles; often operated in the nonmultiplying (ionization chamber) or proportional region with pulse height selected to discriminate against pulses due to beta or gamma rays and to pass only those due to alpha particles.

ALPHA CRUCIS. Ranking thirteenth in apparent brightness among the stars, Alpha Crucis has a true brightness value of 4,000 as compared with unity for the sun. Alpha Crucis is a blue-white, spectral type B star and is located in the constellation Crux (Southern Cross) south of the ecliptic. Estimated distance from the earth is 400 light years. See also **Constellations**.

ALPHA CUTOFF. The frequency at which the alpha (current amplification) of a transistor has fallen to 0.7 (3 decibels) of its low-frequency value.

ALPHA DECAY. The emission of alpha particles by radioactive nuclei. The name *alpha particle* was applied in the earlier years of radioactivity investigations, before it was fully understood what alpha particles are. It is known now that alpha particles are the same as helium nuclei. When a radioactive nucleus emits an alpha particle, its atomic number decreases by $Z = 2$ and its mass number by $A = 4$. The process is a spontaneous nuclear reaction, and the radionuclide that undergoes the emission is known as an *alpha emitter*.

The entire energy released by the transition is carried away by the product nuclei. Therefore, a spectrum of alpha-particle numbers as a function of energy shows a series of distinct peaks, each corresponding to a single alpha-particle transition. To conserve both energy and momentum, the energy must be shared by the two product nuclei, with the daughter nucleus ($^{A-4}Z-2$) recoiling away from the direction of emission of the alpha particle. If E_X and M_X are, respectively, the kinetic energy and mass of the alpha particle and E_R and M_R the kinetic energy and mass of the recoiling product nucleus, the transition energy is $Q = E_\alpha + E_R$; and the kinetic energy of the emitted alpha particle is $E_\alpha = [M_R(M_\alpha + M_R)]Q$.

Almost all radioactive nuclides that emit alpha particles are in the upper end of the periodic table, with atomic numbers greater than 82 (lead), but a few alpha-particle emitting nuclides are scattered through lower atomic numbers. The reason why alpha-particle emitters are limited to nuclides with larger mass numbers is that generally only in this region is alpha-particle emission energetically possible. Most radioactive nuclides with smaller mass numbers emit beta-particle radiation.

See **Particles (Subatomic)**; and **Radioactivity**.

ALPHA EMITTER. A radionuclide that undergoes a transformation by alpha-particle emission.

ALPHA PARTICLE. A helium nucleus emitted spontaneously from radioactive elements both natural and, man-made. Its energy is in the range of 4–8 MeV and is dissipated in a very short path, i.e., in a few centimeters of air or less than 0.005 mm of aluminum. It has the same mass (4) and positive charge (2) as the helium nucleus. Accelerated in a cyclotron alpha-particles can be used to bombard the nuclei of other elements.

See also **Beta Decay**; **Helium** and **Radioactivity**.

ALPHERATZ (α Andromedae). A star formerly allotted to the constellation Pegasus by the Arabs. It is situated at the northeast corner of the great square of Pegasus. The star is a spectroscopic binary with a period of approximately 100 days. See also **Constellations**.

ALPINE (Ecology). Characteristic of mountainous regions between the timberline and the snowline. The term is used with reference to the flora, climate, relief, ecology, etc. of such regions. In a less restrictive sense, the term pertains to high elevations and cold climates.

ALPINE OROGENY. The term for the relatively young orogenic events that occurred in southern Europe and Asia, during which the rocks of the Alps and the remainder of the Alpine orogenic belt were strongly deformed. Most geologists restrict the era to the Tertiary, ending during the Miocene or Pliocene.

ALTAIR (α Aquilae). A star that forms, with β and γ of the constellation Aquila, a well-known line of stars sometimes referred to as the shaft of Aquila. These stars are a conspicuous feature of the early autumn sky. Ranking twelfth in apparent brightness among the stars, Altair has a true brightness value of 11 as compared with unity for the sun. Estimated distance from the earth is $16\frac{1}{2}$ light years. Altair is classified as a white star of spectral type A. See also **Constellations**; and **Star**.

ALTAZIMUTH. An instrument so mounted that it may be rotated about a horizontal and a vertical axis (i.e., rotated in altitude and azimuth);

the earliest type of mounting for astronomical telescopes. Perhaps the most familiar altazimuth instrument is the ordinary surveyor's transit or theodolite.

The great advantage of the altazimuth is the ease with which it may be set up. If the instrument has been properly constructed, the horizontal and vertical axes will be strictly perpendicular to each other, and the only necessary adjustment will be to level the horizontal axis.

The altazimuth instrument is used in the field for laying down azimuth lines and for determining latitude and longitude by measuring altitudes of celestial objects. A few large, fixed altazimuth instruments are in use in observatories for accurate determination of declinations of stars, but for this purpose, the meridian circle is most commonly used.

For ordinary astronomical observing, the altazimuth instrument is less convenient than the equatorial because the diurnal motion of the celestial sphere is parallel to the equator rather than to the horizon, with the result that the instrument has to be moved about both axes to follow the celestial objects. See also **Theodolite**.

ALTERNATING CURRENTS. Electric currents that vary periodically with time. These currents are produced by impressing periodic voltages on an electric system. Alternating voltages are produced by rotating generators called alternators or by electronic devices called oscillators, signal generators or waveform generators. Various alternating waveforms are shown in the accompanying figure. One complete set of positive and negative values is called a *cycle*. The time T of a complete cycle is the *period* and is given in seconds. The *frequency* of a wave is the number of cycles occurring in one second. Thus f, the frequency, $= 1/T$ cycles per second. The angular frequency of the periodic wave is defined as 2π times the frequency or ω (Greek letter omega), the angular frequency, $= 2\pi f$ radians per second. For the sine wave, the instantaneous voltage $e(t) = E_m \cos(\omega t + \alpha)$. The angle α is called the phase angle and is determined by the position of the origin.

The instrument for measuring waveforms is the oscilloscope, which describes a plot on the face of a cathode-ray tube. The vertical deflection of the describing electron beam is proportional to the voltage on the vertical presentation terminals and the horizontal deflection is proportional to the linear sweep-voltage on the vertical presentation terminus. When the wave being observed is repetitive at a fast enough rate, the display appears as a steady figure.

The average value of the sine wave voltage for a complete cycle is 0. The average value for half a cycle is $2E_m/\pi$. The rms (root-mean-square) value of the sine wave voltage is $\sqrt{2}E_m/2 = 0.707E_m$. See Fig. 1.

Through common usage, the expression *alternating current* or ac refers to a current or a voltage that has a waveform closely approximating the sine wave. There are many advantages to the use of sinusoidal voltages such as:

1. Efficient transmission of electrical energy over long distances by stepping up the voltage with static transformers.
2. Simplification in design and reduction in cost of generators and motors.
3. Basic waveform for signal processing in the generation of modulated carriers for communication systems.
4. Signal analysis using the Fourier methods. See **Frequency (Electric) Measurement**.
5. Systems analysis in terms of frequency and phase response. See also **Oscilloscope**; and **Signal Generator**.

Alternating Current Circuits

A circuit is an interconnection of electrical elements consisting of energy sources, resistors, capacitors, and inductors having self and mutual inductance. The steady-state response of a circuit or electrical network to sinusoidal sources is obtained in complex representation. The complex form of a sinusoidal voltage

$$e(t) = E_m \cos(\omega t + \alpha)$$

is

$$E_m \in^{j(\omega t+\alpha)} = (E_m \in^{j\alpha})(\in^{j\omega t})$$
$$= \mathbf{E}_m \in^{j\omega t}, (j = \sqrt{-1})$$

The complex $\mathbf{E}_m = E_m \in^{j\alpha} = E_m \langle \alpha$ is called the phasor voltage in terms of its maximum value. $\mathbf{E} = \mathbf{E}_m\sqrt{2} = 0.707E_m\langle\alpha$, the phasor voltage in terms of its rms or effective value, is called simply the phasor voltage. It can be seen that the instantaneous voltage is the real part of its complex representation. The complex representation of the sinusoidal current

$$i(t) = I_m \cos(\omega + \beta) \text{ is } I_m \in^{j(\omega t+\beta)} = (I_m \in^{j\beta}) \in^{j\omega t} = \mathbf{I}_m \in^{j\omega t}$$

where $\mathbf{I}_m$, the phasor current in terms of its maximum, is $I_m \in^{j\beta} = I_m \langle \beta$. The phasor current $\mathbf{I} = \mathbf{I}_m/\sqrt{2} = 0.707I_m\langle\beta$. Again, the instantaneous value of the current $i(t)$ = real part of $\mathrm{I}_m \in^{j\omega t}$. Phasors are expressed in either polar form, magnitude and angle, or rectangular form, real and imaginary parts.

For an inductance, the voltage

$$e(t) = L\frac{di(t)}{dt}$$

Now $i(t)$ in complex representation is $\mathbf{I}_m \in^{j\omega t}$, so $e(t)$ in complex representation is $\mathbf{I}_m(j\omega L) \in^{j\omega t}$ and

$$\mathbf{E}_m = \mathbf{I}_m(j\omega L)$$

The ratio of the two phasors,

$$\frac{\mathbf{E}_m}{\mathbf{I}_m} = \frac{\mathbf{E}}{\mathbf{I}} = j\omega L = \omega L\langle\frac{\pi}{2} = (\omega L) \in^{j\omega/2}$$

The instantaneous voltage $e(t) = E_m \cos(\omega t + \alpha)$ = real part of

$$\mathbf{I}_m(\omega t) \in^{j(\omega t+\pi 2)} = \mathbf{I}_\mathrm{m}(\omega L)\cos\left(\omega t + \beta + \frac{\pi}{2}\right)$$

So

$$\mathrm{E}_m = \mathrm{I}_m(\omega L)$$

and

$$\alpha = \beta + \frac{\pi}{2}$$

Figure 2 shows the circuit diagram, the sinusoidal waveforms and the phasor diagram. As $E_m = I_m(\omega L)$ then $E_{rms} = I_{rms}(\omega L)$ or the rms value of the voltage across an inductance is equal to $(\omega L) = X_L$, the inductive reactance (given in ohms) multiplied by the rms value of the current through the inductance. The sinusoidal current lags the voltage by $\pi/2$ radians.

For a capacitance, the current

$$i(t) = C\frac{de(t)}{dt}$$

In complex representation,

$$\mathbf{I}_m \in^{j\omega t} = \mathbf{E}_m(j\omega C) \in^{j\omega t}$$

or

$$\mathbf{I}_m = \mathbf{E}_m(j\omega C)$$

$$\frac{\mathbf{E}_m}{\mathbf{I}_m} = \frac{\mathbf{E}}{\mathbf{I}} = \frac{1}{j\omega C} = -\frac{j}{\omega C} = jX_C = \frac{1}{\omega C}\langle\frac{\pi}{2}$$

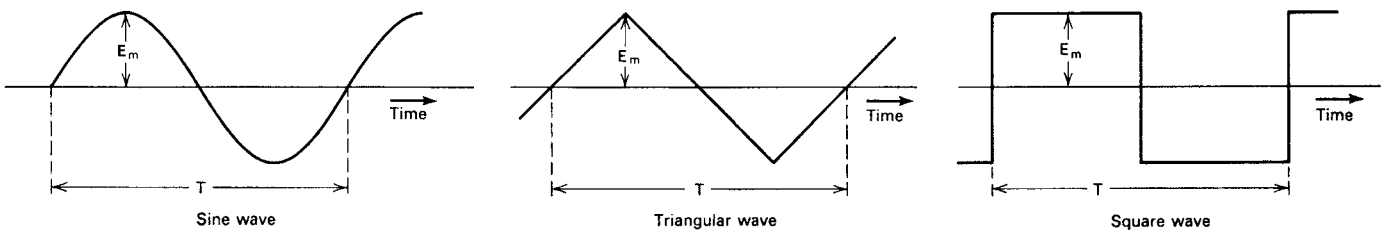

Fig. 1. Fundamental waveforms.

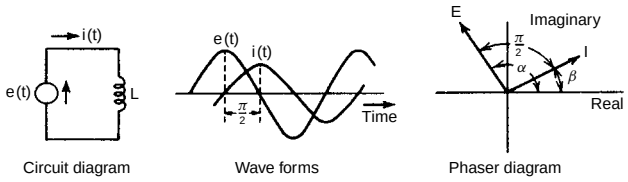

Fig. 2. Case where sinusoidal current lags the voltage by $\pi/2$ radians.

The instantaneous voltage $e(t) = I_m(1/\omega C)\cos(\omega t + \beta - \pi/2)$. Therefore $\alpha = \beta - \pi/2$ and $E_{rms} = I_{rms}(-X_C)$, where X_C, the capacitive reactance, is $-1/\omega C$, or the rms value of the voltage across a capacitor is equal to the magnitude of the capacitive reactance multiplied by the rms current. The sinusoidal current leads the voltage by $\pi/2$ radians. Figure 3 illustrates this case.

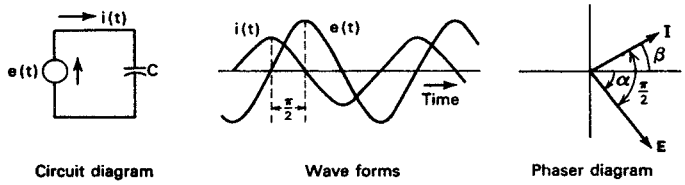

Fig. 3. Case where sinusoidal current leads the voltage by $\pi/2$ radians.

For a resistance, the voltage, $e(t) = Ri(t)$. In the complex representation,

$$\mathbf{E}_m \in^{j\omega t} = R\mathbf{I}_m \in^{j\omega t}$$

or

$$\mathbf{E}_m = \mathbf{I}_m R, \frac{\mathbf{E}_m}{\mathbf{I}_m} = \frac{\mathbf{E}}{\mathbf{I}} = R$$

The instantaneous voltage $e(t) = I_m R\cos(\omega t + \beta)$, where $E_m \div I_m R$ and $\alpha = \beta$.

The rms value of the voltage across a resistor is equal to the product of the current through the resistance and the value of the resistance. The sinusoidal current is in phase with the voltage. Figure 4 illustrates this case.

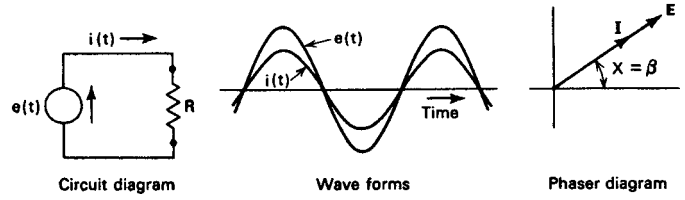

Fig. 4. Case where sinusoidal current is in phase with the voltage.

The responses of a network to sinusoidal sources are determined directly from the general but simple problem of the steady-state response of a network to sinusoidal sources.

Thus for the circuit shown in Fig. 5 with an exponential voltage source $A \in^{st}$, the application of Kirchhoff's laws gives

$$Ri + L\frac{di}{dt} = A \in^{st}$$

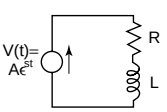

Fig. 5. Circuit with an exponential voltage source.

As the particular integral is the steady state solution,

$$i(t) = \frac{A \in^{st}}{R + sL}$$

For sinusoidal response, using complex representation

$$A \text{ is } \mathbf{E}_m, \quad s = j\omega$$

and

$$i(t) \text{ is } \mathbf{I}_m \in^{j\omega t}$$

The equation for the current to the network becomes

$$\mathbf{I}_m \in^{j\omega t} = \frac{\mathbf{E}_m \in^{j\omega t}}{R + j\omega L}$$

or

$$\mathbf{I}_m = \frac{\mathbf{E}_m}{R + j\omega L}, \mathbf{I} = \frac{\mathbf{E}}{R + j\omega L} = \frac{\mathbf{E}}{\mathbf{Z}} = \mathbf{EY}$$

The impedance of the network (sometimes referred to as the complex impedance) is

$$\mathbf{Z} = \frac{\mathbf{E}_m}{\mathbf{I}_m} = \frac{\mathbf{E}}{\mathbf{I}}$$

For this network, the impedance is $R + j\omega L$ or its real part is the Resistance R and its imaginary part, the inductive reactance ωL. The admittance of the network, $\mathbf{Y}$, is equal to $\mathbf{I}_m/\mathbf{E}_m = \mathbf{I}/\mathbf{E} = 1/\mathbf{Z}$. For this network, the admittance is $1/(R = j\omega L))$. As

$$\mathbf{I}_m = \frac{\mathbf{E}_m}{R + j\omega L} = \frac{E_m < \alpha}{\sqrt{R^2 + (\omega L)^2}\langle\theta} = \frac{E_m < (\alpha - \theta)}{\sqrt{R^2 + (\omega L)^2}}$$

So the instantaneous current

$$i(t) = \frac{E_m}{\sqrt{R^2 + (\omega L)^2}}\cos(\omega t + \alpha + \theta), \theta = \tan^{-1}\frac{\omega L}{R}$$

$$= I_m\cos(\omega t + \beta)$$

$$I_m = \frac{E_m}{\sqrt{R^2 + (\omega L)^2}}$$

or

$$I_{rms} = \frac{E_{rms}}{\sqrt{R^2 + (\omega L)^2}}$$

and $\beta = \alpha - \theta$ or the current lags the voltage by the angle θ. Figure 6 shows the waveform and the phasor diagram.

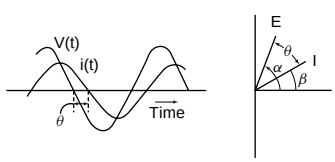

Fig. 6. Waveform and phasor diagram for case of Fig. 5.

For the series *R-L-C* circuit,

$$Ri + L\frac{di}{dt} + \frac{1}{C}\int i\,dt = A \in^{st}$$

The particular integral is

$$i(t) = \frac{A \in^{st}}{R + sL} + \frac{1}{sC}$$

This relation may be written directly from the network, labeling each element as shown in Fig. 7 and calculating the current as if it were a dc circuit with each element equivalent to a resistor. For the sinusoidal response

$$\mathbf{I} = \frac{\mathbf{E}}{R + j\omega L + 1/j\omega C} = \frac{\mathbf{E}}{R + j(X_L + X_C)} = \frac{\mathbf{E}}{\mathbf{Z}}$$

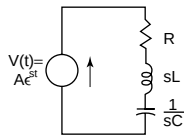

Fig. 7. Example of labeling each element in network.

and

$$\mathbf{Z} = R + j(X_L + X_C) = \sqrt{R^2 + (X_L + X_C)^2}\langle\theta$$

where

$$\theta = \tan^{-1}\frac{X_L + X_C}{R}$$

and

$$i(t) = \frac{E_m}{\sqrt{R^2 + (X_L + X_C)^2}}\cos(\omega t + \alpha - \theta)$$

So

$$I_{rms} = \frac{E_{rms}}{\sqrt{R^2 + (X_L + X_C)^2}} \text{ and } \beta = \alpha - \theta$$

When $|X_L| > |X_C|, \theta$ is positive and the current in the circuit lags the impressed voltage, and when $|X_L| < |X_C|, \theta$ is negative and the current leads the impressed voltage.

A parallel *R-L-C* circuit having the same current source as in Fig. 7 is shown in Fig. 8.

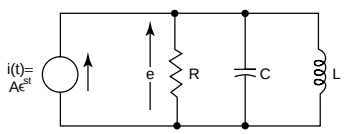

Fig. 8. Parallel *R-L-C* circuit with a current source.

The response of a linear network to a periodic source function that is not sinusoidal may be determined by describing the function as a sum of sine waves in a Fourier analysis. The sum of responses to each sine wave is the total response.

The instantaneous power supplied to an ac circuit is $p = ei$, and the average power is

$$P_{av} = \frac{1}{T}\int_0^T ei\,dt$$

ALTERNATING GRADIENT FOCUSING. This principle, discovered independently by Christofilos in 1950 and by Courant, Livingston, and Snyder in 1952, is based on the observation from geometrical optics that a combination of a convex lens and a concave lens of equal focal length have a net focusing effect. This type of focusing of moving charged particles is accomplished by appropriately shaped magnetic fields. But, since magnetic fields cannot focus simultaneously in both the vertical and horizontal planes that can be constructed through a line representing the direction of motion of a beam of charged particles, alternate lenses that focus first in the horizontal direction and then in the vertical direction are needed. This can be accomplished for an external beam of charged particles by pairs of quadrupole magnets. The same principle has been applied to the magnetic fields in particle accelerators. In a synchrotron, for example, a section of magnet focuses axially and defocuses radially, while the following section defocuses axially and focuses radially. See **Particles (Subatomic)**.

ALTERNATING GROUP. The group of even permutations of n objects. See **Permutation**.

ALTERNATING SERIES. A series whose terms are alternately positive and negative. See **Series**.

ALTERNATION OF GENERATIONS. A term used to describe the alternation of two distinct body forms, one reproducing sexually and one reproducing asexually, in the life cycle of a plant or animal. A typical example is to be found in the hydrozoan coelenterate, *Obelia*. See Fig. 1. One generation, the hydroid stage, reproduces asexually by budding and forms a colony consisting of a stalk bearing many polyps. As the colony grows older, reproductive polyps are formed which produce buds that grow into small jellyfish known as medusae. Some polyps produce male and others produce female medusae. These medusae break free of the polyp and swim in the water. The males produce sperms, which swim to the eggs produced by the females. The zygote grows into a ciliated larva, which swims around for a time and then settles down and becomes attached. It then grows into a hydroid stage.

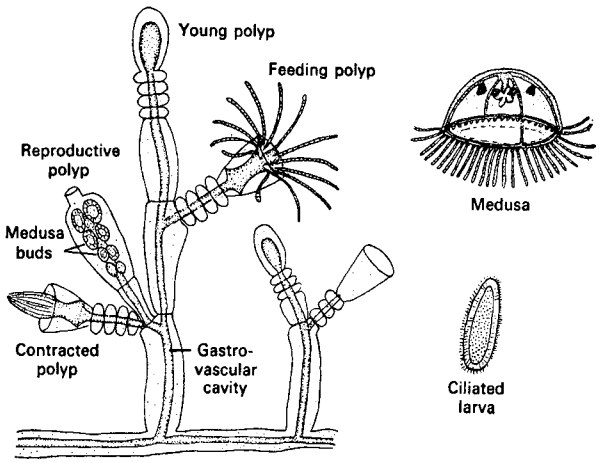

Fig. 1. The life cycle of *Obelia*.

Parasitic flatworms, such as flukes and tapeworms, and the malarial parasite (*Plasmodium*) are among the other animals that have alternation of generations.

In all except some of the simplest plants there is alternation of generations. The sporophyte generation reproduces asexually by means of spores. These spores are produced by a series of two special cell divisions known as meiosis, which reduces the chromosome number to half, the haploid number. A spore grows into a gametophyte generation, which will have the haploid number. Gametes are produced by the gametophyte, and when these unite a zygote is formed with the diploid number. The zygote then grows into a sporophyte generation.

As plants become larger and more complex, there is a tendency toward a reduction in the size of the gametophyte generation. In liverworts,

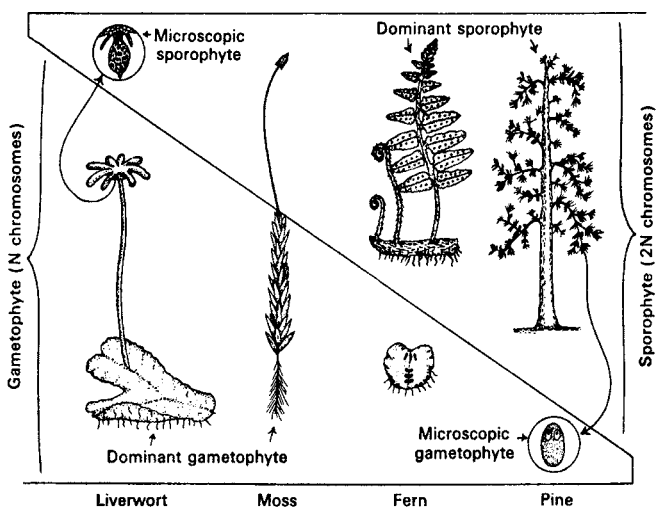

Fig. 2. Alternation of generations is demonstrated by the gradual shift of emphasis from the dominant gametophyte generation (exemplified by the liverworts) to the dominant sporophyte in the seed plants (exemplified by the pine).

the sporophyte is microscopic in size; in the mosses the gametophyte is still dominant, but there is a clearly visible sporophyte; in the ferns the sporophyte is dominant, but the gametophyte is still present as a distinct and separate plant; in the seed plants the gametophyte is microscopic in size. See Fig. 2.

ALTERNATOR. An electromotive force is generated in a conductor when it is moved so as to cut the lines of force between the poles of a magnet. The elementary principle of a simple two-pole, single-phase alternator is shown in Fig. 1. When the magnet revolves it will carry with it lines of force which will cut the conductor, which is a wire loop embedded in the stationary portion called the armature, and will generate ac.

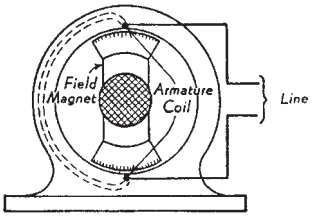

Fig. 1. Elementary alternator.

This elementary principle must be expanded in several directions if a practical generator of ac is to be had. First, the rotating part, or rotor, must have magnetic strength in excess of that which could be obtained from a simple permanent magnet. In other words, the poles must be formed by electromagnets whose excitation, in the form of dc, must be carried to the rotor through slip-ring connections. The rotor is called the field, and the current it uses is called the field current. In high-speed steam turbine-driven alternators as few as two poles are often used, while in slow-speed water-turbine units the number is frequently nearly 100. The stationary part, called the stator, or armature, usually has three sets of overlapping coils, connected in three separate circuits. These three circuits, or phases, are usually connected in one or the other ways shown in Fig. 2. The *Y* connection is preferred because of the usefulness of the neutral point, and the fact that the line voltage is $\sqrt{3}$ times the phase voltage, whereas it is only equal to the phase voltage in Δ connection. The neutral point is connected to the fourth wire of a four-wire, three-phase system, and left unconnected, or grounded, in the three-wire system. Several advantages are realized by making the rotating part the field, and the stationary part the armature. The ac may be generated at very high voltages because it is not necessary to connect it through movable contacts as would be the case if the armature revolved. It is not necessary to conduct high-load currents through slip rings and brushes if the armature is fixed. The armature conductors can be very rigidly braced in position, and may be much better disposed than if they were required to be in the rotor.

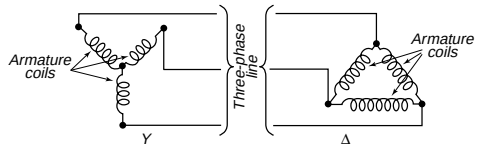

Fig. 2. Comparison of *Y* and *Delta* connections of three-phase alternator windings.

Engine and hydraulic turbine-driven alternators are in the slow-speed class, and are characterized by large diameter, short length, and many poles. The steam turbine-driven alternator is a high-speed machine having a length larger than its diameter. Standard speeds of turbine-driven alternators range from 1200 to 3600 rpm, with 1800 rpm very common practice.

Basically, the alternator is a device for converting mechanical into electrical energy. While it is able to do this with a high degree of efficiency, it does suffer the following losses:

1. Friction and windage from bearings, brushes, and fan action of the rotor.
2. Core loss, which is the result of eddy currents and hysteresis in the iron core.
3. Resistance heating loss in the armature and field conductors.
4. Resistance loss of the field rheostat.
5. Exciter loss.
6. Ventilation loss.

Practically all generator losses appear as heat in and about the windings, and to maintain these at a safe working temperature, a cooling medium must be employed. Air has been the medium generally used. The rotor may or may not be able to produce its own fan action, depending on the size, speed, and construction of the rotor. Ventilating air frequently has to be brought through a duct and discharged through the alternator. Hydrogen is rapidly becoming a common cooling medium as it is much more effective and produces less windage loss. For its use the generator must be totally enclosed and gas-tight. To supply the dc for the field, a source of dc at 110–250 volts is necessary. This is delivered from a small dc generator called the exciter. The exciter may be driven from an extension of the alternator shaft, or it may be driven by some independent means, such as motor or engine.

When alternators are operated in parallel, the division of load between them is not accomplished by changing the generated voltage, as in dc generators, but by changing power input from the prime mover through the adjustment of the engine or turbine governor.

ALTI-ELECTROGRAPH. See **Meteorology**.

ALTIMETER. An altimeter is an instrument that determines the altitude of an object with respect to a fixed level. The traditional altimeter found in most aircraft works by measuring the air pressure from a static port in the airplane. Air pressure decreases with an increase of altitude — about one millibar (0.03 inches of mercury) per 27 feet (8.23 m) close to sea level. The altimeter is calibrated to show the pressure directly as altitudes, in accordance with a mathematical model defined by the International Standard Atmosphere (ISA) http://www.aeromech.usyd.edu.au/aero/atmos/atmtab.html.

There are several types of altimeters: 1) the pressure altimeter, which measures barometric pressure and converts it to altitude above sea level when referenced to the existing measured sea level barometric pressure, or to pressure altitude when referenced to a standard pressure; 2) the radio or radar altimeter, which deduces altitude by measuring the time it takes a radio signal to travel from a transmitter to the underlying surface and back to the receiver; this type of altimeter provides the pilot with the actual distance between the plane and the ground, as opposed to a barometric altimeter which only provides altitude above sea level; and 3) the Global Positioning System (GPS), which determines altitude by measuring time of travel of radio signals between GPS-equipped satellites and the receiver. See also **Altimetry**; and **Global Positioning System (GPS)**.

Scientific Uses

A number of satellites (Seasat and TOPEX/Poseidon) used exotic dual-band radar altimeters to measure spacecraft height above the ocean surface. That measurement, coupled with orbital elements (possibly from GPS), enables determination of the topography. The two lengths of radio waves permit the altimeter to automatically correct for varying delays in the ionosphere.

Over water, detailed satellite altitude information has proven amazingly useful. Humps in the water indicate gravitational concentrations, permitting a computer program to construct a map of undersea features such as mountains. The altimeters can also measure wave heights, wave directions, and wave spectra. This information permits computer programs to measure the speed of ocean currents and produce detailed maps of wind speeds and directions at the surface, even in extremely stormy conditions.

ALTIMETRY. The technique of using air pressure to measure altitude. In altimetry there is a precisely ordered atmosphere called the *Standard Atmosphere* in which there is an exclusive value of altitude associated with a given value of air pressure. An altimeter converts static pressure into altitude. It is this precise and mathematically rigid relationship between static air pressure and altitude that the altimeter incorporates into its mechanism.

The standard atmosphere is defined by the following parameters:

(1) Zero pressure altitude corresponds to:

29.9213 inches of mercury

1013.250 millibars

760.000 millimeters of mercury

(2) Temperature at zero pressure altitude is 15 °C, which is equivalent to 288.16 K.
(3) Density of air at zero pressure altitude is 0.0012250 gram per cubic centimeter.
(4) The rate of temperature decrease with altitude is 6.5° per kilometer from zero pressure altitude up to 11 kilometers.
(5) The temperature at 11 kilometers is −56.5 °C.
(6) The temperature from 11 kilometers up to 25 kilometers is constant at −56.5 °C.
(7) The acceleration of gravity is everywhere 980.665 centimeters/sec^2.*
(8) There is no water vapor in the physical make-up of the atmosphere.*
(9) There is perfect obedience to the perfect gas law and the hydrostatic equation.*

In this concept of standard atmosphere, there is a unique value of density, pressure, and temperature at each altitude. The relationship between pressure and height is given by:

$$H = \frac{T_0}{\beta}\left[1 - \left(\frac{P_0}{P}\right)^{R\beta/g}\right]$$

where P_0 = the reference pressure which in practice is usually one of the following:

(1) Mean sea level pressure
(2) Field pressure
(3) 29.92 inches of mercury (1013.3 millibars)

T_0 = the standard atmosphere temperature at P_0
β = the temperature rate of decrease with altitude
R = the gas constant for standard air
g = acceleration due to gravity
P = the sensed and measured pressure by the altimeter
H = the altitude corresponding to P in the standard atmosphere

Millibars of pressure are used in much of international aviation instead of inches of mercury, but the latter is still the common usage in much of North America.

Toussaint's Formula. A rule proposed by Toussaint for the linear decrease of temperature with height in the atmosphere for which the temperature at mean sea level is 15 °C is given by

$$t = 15 - 0.0065z$$

where t is the temperature in degrees centigrade and z is the geometric height in meters above mean sea level. Toussaint's formula is used to determine temperature below 11,000 meters in the ICAO standard atmosphere.

Field Pressure. This is the atmospheric pressure measured and observed at the elevation of the airport or weather observatory in the real atmosphere by use of a mercurial barometer or a calibrated aneroid instrument. All pressure-related functions in altimetry must start with field pressure.

Field pressure *reduction to mean sea level* relates a calculated atmospheric pressure at sea level to field pressure by application of standard atmosphere relations. Field elevation above mean sea level is known and field pressure is measured. The pressure increment dictated by the standard atmosphere is added to the field pressure to obtain a value for mean sea level pressure.

Mean Sea Level Pressure. This is used extensively in altimeter-measured altitudes above sea level up to 18,000 feet (5486 meters). Mean sea level pressure is also known as *altimeter setting*, to which altimeters in airborne aircraft are set while flying below 18,000 feet (5486 meters).

Pressure Altitude. This is height in the standard atmosphere measured positively upward from the zero elevation of 29.92 inches of mercury (1013.3 millibars). An altimeter carrying a reference pressure of 29.92 inches of mercury (1013.3 millibars) will display pressure altitude.

Altimeter. A very sensitive instrument that converts static air pressure to altitude according to the precise relationship of the pressure and height in the standard atmosphere. There is a *reference pressure* adjustable setting on the altimeter that can be set to any reference pressure within the operating range of the altimeter. The altimeter measures altitude positively upward (negatively downward) from the level of the reference setting. In practice, three reference settings are predominantly used:

(1) *Reference setting at field pressure* will cause the altimeter to measure altitude positively upward from the level of the airport. When sitting on the airport, an aircraft altimeter will read zero.

(2) *Reference setting at mean sea level pressure*, also called "altimeter setting," will cause the altimeter to read altitude above mean sea level.

(3) *Reference setting at 29.92 inches of mercury* (1013.3 millibars) will cause the altimeter to measure altitude positively upward from the level where a pressure of 29.92 inches of mercury (1013.3 millibars) prevails in the real atmosphere. Altitude readings obtained with the reference set at 29.92 inches of mercury (1013.3 millibars) are known as "pressure altitude."

The altimeter may be an aneroid barometer calibrated to read in feet of altitude instead of barometric pressure. It thus reads pressure, not density, altitude. The heart of this instrument is a circular evacuated capsule, one face of which is fastened to the case, while the other is attached through a system of multiplying levers (terminating in a chain wrapping around the spindle) to a spindle carrying a pointer which moves over the scale. A U-shaped spring holds the capsule distended and atmospheric pressure tends to collapse it.

When mounted in an airplane climbing to higher altitudes, the capsule is subjected to decreasing atmospheric pressure, allowing the spring to distend the capsule and move the pointer. A small hairspring keeps the mechanism taut and the pointer will move upon the slightest movement of the capsule face in either direction.

The instrument may be made to indicate altitude above any given point, e.g., the airport runway, by rotating the dial containing the scale until the pointer registers with zero altitude, this being done when the airplane is on the runway. A knob having a pinion engaging a gear on the periphery of the dial makes this adjustment.

Vertical Separation. The vertical separation of airborne aircraft is accomplished by use of onboard altimeters and the application of altimetry.

(1) Below 18,000 feet (5486 meters), all aircraft have their altimeters set to a common altimeter setting (mean sea level) in a given traffic control area. If there are deviations from the real altitude above sea level, all aircraft carry the same deviation.

(2) Above 18,000 feet (5486 meters), all aircraft use a reference setting of 29.92 inches of mercury (1013.3 millibars) and operate on pressure altitude.

Terrain clearance when using altimeter-indicated altitude requires some precaution in air that is colder than the standard atmosphere. Mountain peaks have fixed real heights, which obviously must be exceeded.

(1) If the reference setting is mean sea level pressure, the altimeter indicates altitude above sea level. When the real atmosphere is colder than the standard atmosphere, the altimeter will display a reading *too high*, i.e., the aircraft will have *less* real altitude than shown on the altimeter.

(2) If the reference setting is 29.92 inches of mercury (1013.3 millibars), the altimeter indicates altitude above the level where this value of P prevails. In addition to the cold air deviation, an additional caution is needed. When sea level pressure is less than 29.92 inches of mercury (1013.3 millibars), the altimeter starts counting altitude from *below sea level*. The altitude displayed by the altimeter will be too high by reason of the below-standard sea level pressure; and additionally may be in error because the air is colder than standard air.

(*Mean Sea Level*) — The average height of the sea surface, based upon hourly observation of the tide height on the open coast or in adjacent waters that have free access to the sea. These observations are to have been made over a "considerable" period of time. In the United States, mean sea level

* It should be stressed that the foregoing statements are part of the arbitrary, but important definition of standard atmosphere and should be interpreted in this context. For a more detailed definition of standard atmosphere, see **Atmosphere (Earth)**.

(MSL) is defined as the average height of the surface of the sea for all stages of the tide over a 19-year period.

(*Mean Sea Level Pressure*) — The value assigned to surface pressure of the standard atmosphere; 29.92 inches of mercury; or 1013.3 millibars.

Other Forms of Altimeters. A radio altimeter is an electronic instrument that may operate on one of the following principles: (1) pulse radar techniques which measure height in terms of the transit time of the radar pulse; (2) continuous-wave radar which measures height in terms of the phase difference between the transmitted and received signals; and (3) the variation of the electrical capacitance between aircraft and ground.

For references see entries on **Climate**; and **Meteorology**.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

ALTITUDE. The term *altitude* is used synonymously for height, or distance above the surface of the earth. The altimeter is used in aviation to measure the altitude of a plane above sea level.

In astronomy and navigation the altitude of a celestial object is that coordinate in the horizontal system of spherical coordinates that is measured in the plane of the vertical circle through the object from the horizon to the object. Altitude is probably the most frequently measured of all celestial coordinates since it is universally used in celestial navigation to find lines of position for the determination of the location of a ship at sea, or an aircraft in the air. Altitude is also measured by geodetic surveyors for accurate determination of latitude and is used by astronomers for determination of the declinations of the stars.

The principal points of high and low elevation on the earth's surface are given in the entry on **Earth**.

ALTMAN, SIDNEY (1939–). Sidney Altman was a Canadian-born molecular biologist who made seminal discoveries regarding the catalytic properties of RNA molecules.

The son of immigrant workers in Montreal, Canada — his father owned a grocery store and his mother worked at a textile mill — Sidney Altman grew up with a deep appreciation for the value of education as a means of success. An unexpected turn of events gave him the opportunity to attend the Massachusetts Institute of Technology (MIT) for his undergraduate studies and he graduated in 1960 with a degree in physics. He began graduate studies in physics at Columbia University, but soon left and went to the University of Colorado, where he enrolled as a student of biophysics and obtained his PhD in 1967. He spent the next few years in research fellowships at Harvard University and at the Medical Research Council Laboratory of Molecular Biology at Cambridge in the UK. In 1971 he joined the faculty at Yale University and to date still holds a full-time appointment there.

Altman is best known for his discovery of the catalytic properties of RNA molecules, for which he received a share in the 1989 Nobel Prize for Chemistry along with Thomas Cech. This discovery was a crucial milestone in the history of molecular biology as it upset conventional wisdom and overturned most of the prevailing notions of the functions of various biological molecules. Until Altman and Cech reported their findings, biologists believed that all biological catalysis occurred due to proteins called enzymes. But while investigating the process of transcription and translation in living systems, Altman found that a specific step in RNA transcription was in fact catalyzed by an RNA molecule. This previously unknown species of RNA was subsequently dubbed a "ribozyme" to reflect its enzymatic properties. These findings have offered very valuable insights into our understanding of the molecular origins of life and evolution. With their twin capabilities of replication and catalysis RNA molecules were very likely the first macromolecules in living organisms. The discovery of ribozymes, and the potential to engineer various new types of these molecules, also opened doors to new techniques and capabilities in genetic engineering. See also **Cech, Thomas R. (1947–Present)**.

ALTOCUMULUS. See **Clouds and Cloud Formation**.

ALTOSTRATUS. See **Clouds and Cloud Formation**.

ALUM. A series (*alums*) of usually isomorphous crystalline (most commonly octahedral) compounds in which sulfate is usually the negative ion. Alums have the general formula $M^{I}\ M^{III}\ (AX_4)\cdot 12H_2O$. The first is potassium or a higher alkali metal (sodium alums are rare) or thallium(I) or ammonium (or a substituted ammonium ion) and the second is a tripositive ion of relatively small ionic radius (0.5–0.7 Å). The tripositive ions of larger ionic radius such as the Lanthanides form double sulfates, but not alums. The tripositive ions in alums, in roughly the order of number of known compounds, are aluminum, chromium, iron, manganese, vanadium, titanium, cobalt, gallium, rhodium, iridium, and indium.

The term *alum*, itself, refers to potassium alum, potassium aluminum sulfate, $KA1(SO_4)_2\cdot 12H_2O$. Other common alums are ferric ammonium alum, $NH_4\ Fe(SO_2)_2\cdot 12H_2O$, and sodium chrome alum, $NaCr(SO_4)_2 12H_2O$.

ALUMINA. See **Adsorption**; and **Bauxite**.

ALUMINUM. [CAS: 7429-9-05] Chemical element symbol Al, at. no. 13, at. wt. 26.98, periodic table group 13, mp $660 \pm 1\,^{\circ}C$, bp $2452 \pm 15\,^{\circ}C$, sp gr 2.699. In Canada and several other English-speaking nations, the spelling of the element is *aluminum*. The element is a silver-white metal, with bluish tinge, capable of taking a high polish. Commercial aluminum has a purity of 99% (minimum), is ductile and malleable, possesses good weldability, and has excellent corrosion resistance to many chemicals and most common substances, particularly foods. The electrical conductivity of aluminum (on a volume basis) is exceeded only by silver, copper, and gold. First ionization potential, 5.984 eV; second, 18.823 eV; third, 28.44 eV. Oxidation potentials, $Al \rightarrow Al^{3+} + 3e^{-}$, V; $Al + 4OH^{-} \rightarrow AlO_2{}^{-} + 2H_2O + 3e^{-}$, 2.35 V. Other important physical properties of aluminum are given under **Chemical Elements**.

Aluminum occurs abundantly in all ordinary rocks, except limestone and sandstone; is third in abundance of the elements in the earth's crust (8.1% of the solid crust), exceeded only by oxygen and silicon, with which two elements aluminum is generally found combined in nature; present in igneous rocks and clays as aluminosilicates; in the mineral cryolite in Greenland as sodium aluminum fluoride Na_3AlF_6; in the minerals corundum and emery, the gems ruby and sapphire, as aluminum oxide Al_2O_3; in the mineral bauxite in southern France, Hungary, Yugoslavia, Greece, the Guianas of South America, Arkansas, Georgia, and Alabama of the United States, Italy, Russia, New Zealand, Australia, Brazil, Venezuela, and Indonesia as hydrated oxide $Al_2O(OH)_4$; in the mineral alunite or alum stone in Utah as aluminum potassium sulfate $Al_2(SO_4)_3\cdot K_2SO_4\cdot 4Al(OH)_3$. See also **Bauxite**; and **Cryolite**.

Uses. Because of its corrosion resistance and relatively low cost, aluminum is used widely for food-processing equipment, food containers, food-packaging foils, and numerous vessels for the processing of chemicals. Because of the presence of aluminum in soils and rocks, there are natural traces of the element in nearly all foods. The processing of foods in copper vessels will cause destruction of vitamins, whereas aluminum does not accelerate the degradation of vitamins. Aluminum foil has been used to cover severe burns as a means to enhance healing. Because of its good electrical conductivity (exceeded only by gold, silver and copper), aluminum is used as an electrical conductor, particularly for high-voltage transmission lines. For the same conductance, the weight of aluminum required is about one-half that of annealed copper. The greater diameter of aluminum conductors also reduces corona loss. But, because aluminum has about 1.4× the linear temperature coefficient of expansion as compared with annealed copper, the changes in sag of the cable are greater with temperature changes. For long spans requiring high strength, the center strand may be a steel cable, or supporting steel cables may be used. Aluminum is used for bus bars because of its large heat-dissipating surface available for a given conductance.

Aluminum alloys readily with copper, manganese, magnesium, silicon, and zinc. Many aluminum alloys are commercially available. See also **Aluminum Alloys and Engineered Materials**.

Because aluminum, particularly in alloys, combines strength with light weight, it has been a favorite construction material for transportation equipment, such as airplanes, the early dirigibles, and parts of rail cars. With the emphasis on fuel economy during the past decade or two, the automotive industry has become a major user of aluminum alloys. For example, important developments include cast-aluminum engine blocks with metallurgically bonded-in-place cylinder liners, cast-spun wheels, aluminum space frames, and auto radiators. The first mass production

of aluminum radiators occurred in the 1980s (Ford Motor Co.) and it is predicted that nearly all Ford vehicles will feature aluminum radiators by the mid-1990s. Of course, other auto firms worldwide are also actively pursuing the metal because of its light weight and other attractive properties.

The applications of aluminum are growing larger and more varied with the introduction of advanced materials engineering techniques, including sandwich-type construction, laminates, aluminum powder metallurgy, and composite technology.

Discovery and Early Production. Although aluminum was predicted by Lavoisier (France) as early as 1782, when he was investigating the properties of aluminum oxide (alumina), the metal was not isolated until 1825 by H.C. Oersted (Denmark). Oersted obtained an impure aluminum metal by heating potassium amalgam with anhydrous aluminum chloride, followed by distilling off the mercury. Using similar methods, Woehler (Germany) produced an aluminum powder in 1827. In 1854, Deville (France) and Bunsen (Germany) separately but concurrently found that aluminum could be isolated by using sodium instead of potassium in the amalgam of Oersted and Woehler. Deville exhibited his product at the Paris Exposition of 1855, after which Napoleon III commissioned Deville to improve the process and lower the cost. Because of improved processing techniques, the price declined from $115 to $17 per pound ($254 to $38 per kilogram) by 1859, with numerous plants throughout France. The price was further reduced to $8 per pound ($17.60 per kilogram) by 1885. The first breakthrough for production of aluminum on a large scale and at a much lower cost occurred as the result of experimentation by Hall (Oberlin, Ohio) who found that metallic aluminum could be produced by dissolving Al_2O_3 (alumina) in molten $3NaF{\cdot}AlF_3$ (cryolite) at a temperature of above 960 °C and then passing an electric current through the bath. Heroult (France) independently discovered the same process.

Contemporary Production Methods. For many years the electrolytic process has dominated. The major difference found in aluminum production plants relate to the design of the electrolytic cells. Basically, the cells are large carbon-lined steel boxes. The carbon lining serves as the cathode. Separate anodes are immersed in the bath. The electric circuit is completed by passage of current through the bath. Thus, the alumina is decomposed into aluminum and oxygen by action of the electric current. The molten aluminum collects at the bottom of the cell from which it is siphoned off periodically. The released oxygen combines with carbon at the electrodes to form CO_2. The bath is replenished with alumina intermittently. The carbon anodes must be replaced periodically. Additional cryolite also is required to make up for volatilization losses. The several reactions which occur during electrolysis still are not fully understood.

Energy requirements for aluminum production in modern plants approximate 6 to 8 kilowatt-hours per pound (13.2 to 17.6 kilowatt-hours per kilogram). Per weight unit of aluminum produced, 0.4 to 0.6 weight units of carbon, 1.9 weight units of alumina, and 0.1 weight unit of cryolite are required. One form of electrolytic cell is shown in Fig. 1.

An estimate (1987) showed that the aluminum industry accounts for nearly 1.5% of the annual world energy consumption. Because of the need to conserve energy and concurrently to alleviate (even to a small extent) the disposal of solid waste materials, a program was initiated in some industrial nations to collect and recycle the aluminum cans used mainly by the carbonated beverage industry. The program has proved to be more successful than originally predicted. As of 1990, over one-half of the aluminum beverage cans are recycled in the United States. See Figs. 2 and 3. Efforts also have been made to reduce the amount of aluminum needed for each beverage can. The thickness of the aluminum can body has been reduced from an average weight of 21 grams/can in 1972 to approximately 15 grams/can in 1992. Can manufacturers have developed new designs that retain strength while reducing the amount of metal needed. In one innovation, the top of the can was "necked in" — first one, then two, three, and four times. Each successive necking down of the end lowered the weight of the can. By 1990, the average weight/can had been reduced by at least 26%.

Because of production process improvements, the cost of aluminum has been reduced by many fold over the past century. The demographics of aluminum production have changed markedly in recent years. Since 1982, the virgin metal producers in the United States have closed down or abandoned seven of the older, less-efficient, and higher-cost reduction plants. American producers have gone to other countries to build new modern plants using the most recently developed technology for large

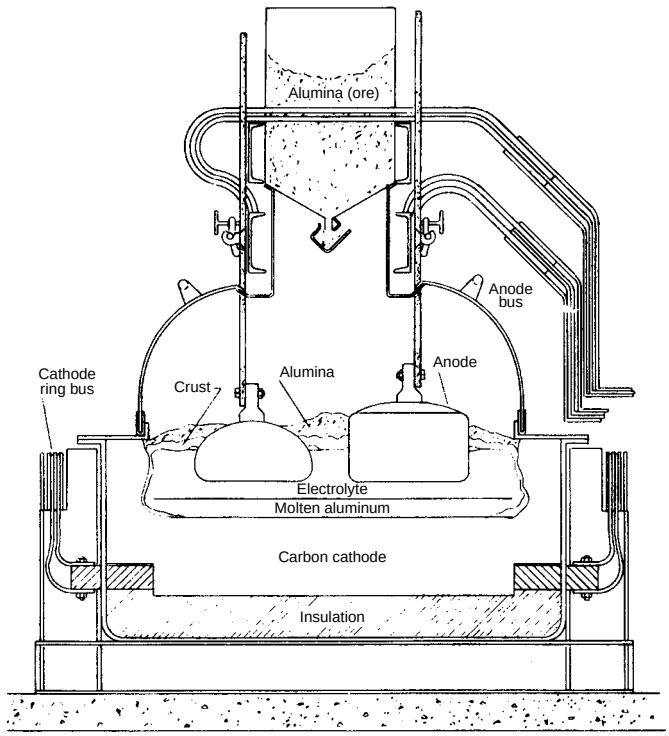

Fig. 1. Aluminum electrolytic reduction cell of the pre-bake type. The anodes are constructed of separate blocks of carbon which have been pre-baked. There is a lead to the main bus bar from each block. (*Reynolds Metals Company*.)

Fig. 2. Recycling of aluminum beverage cans and other scrap saves nearly 95% of the energy required when producing the virgin metal from ore. Approximately 50% of the metal processed in 1990 was recycled from scrap. (*Reynolds Aluminum Recycling Company*.)

electrolytic cells. New generation electrolytic cells operate at very high current densities (180,000–275,000 amperes). These cells will produce four times the output of many existing cells while using 25% less energy.

The principal aluminum-producing areas of the world, in addition to the United States and Europe, are Canada, Venezuela, Brazil, Norway, Australia, and the Republic of the Congo. In the United States the remaining plants are located in the states of Washington, Oregon, and New York, along the Mississippi, and where water power generation is still available at somewhat reduced cost.

In 1960, 90% of world capacity was held by private enterprises. That percentage had dropped to 60% in 1985. The trend is to greater

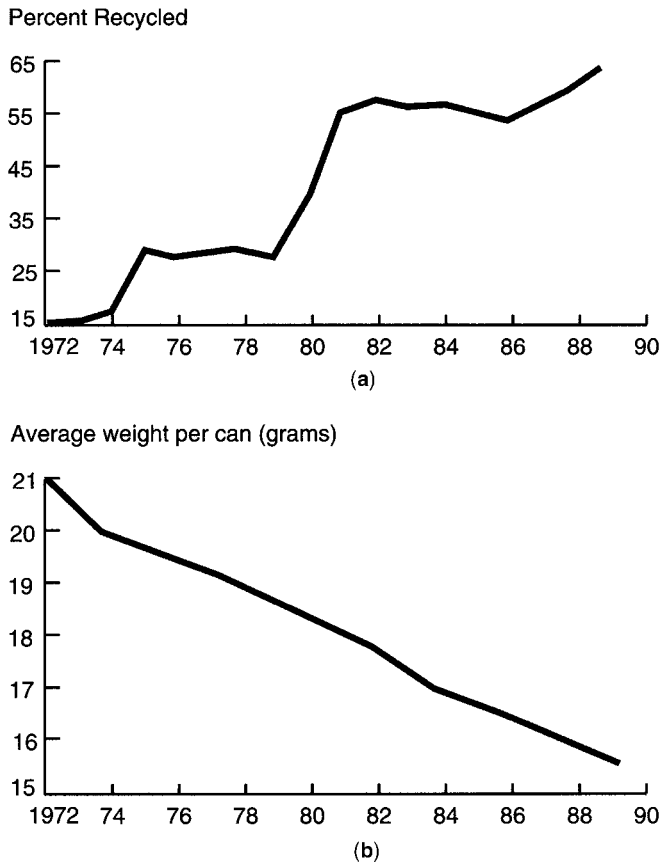

Fig. 3. Steps to conserve aluminum and the electrical power to produce it: **(a)** Percent of aluminum cans recycled (1972–1990); **(b)** average weight of beverage can (grams) (1972–1990). (*Source*: *Aluminum Association*, Washington, DC.)

governmental participation in Latin America. Africa, the Mideast, and Asia. Fifty percent of Western World capacity is government sponsored, primarily in Europe and Latin America. Six corporate groups account for 50% of aluminum production. These are Alcan, Alcoa, Reynolds, Kaiser, Pechiney, and Alusuisse. They possess 40% of the bauxite capacity for alumina and aluminum. All are integrated from mine to ultimate consumer. Australia is the world's largest producer of bauxite.[1]

By 1995, Australia will probably be one of the world's three largest aluminum producers. At present, it supplies one-third of the world's bauxite. New smelter construction underway is expected to boost the world production by two million tons (1.8 million metric tons). New Zealand also has a good potential. Australia has coal reserves estimated at 1500 years.

It is also projected that Venezuela, because of its abundance of hydropower, will become a major aluminum producer. During the past decade, Brazil has attracted considerable interest because of its vast reserves of good quality bauxite and hydropower. The Tucurui hydroelectric power facility will double its output by 1995.

The People's Republic of China is modernizing with the help and technology of foreign companies to bring its production to over 500,000 metric tons.

Most of the increased capacity for virgin aluminum production for the past two and a half decades has occurred outside the continental United States. The annual growth rate for the aluminum industry during this period is estimated at about 1.6%. The projected U.S. growth rate is about 1% per year, as contrasted with $2\frac{1}{4}$% worldwide. U.S. consumption is about 50 pounds (22.5 kg) per person per year. World consumption has doubled about every 20 years. The developed nations (North America, Western Europe, Japan-Oceania) account for two-thirds of world consumption of aluminum (1991).

[1] Firms participating in the development of Australian production capacity include Alcan, Alcoa, Kaiser, Comalco, Alumax, Reynolds, Pechiney and several Japanese companies.

Thermal Reduction Process. Because of the large electric power requirements of the electrolytic process, an effort has been underway for several years to cut production costs. The thermal process, including the use of electric arc furnaces, make it possible to achieve a greater concentration of electric energy in the refining process. Commercial electric furnace processes are fed with bauxite and clays (kaolin or kyanite or partially refined bauxite mixed with carbon or charcoal in briquette form). An electric dc or ac arc is used. To date, this process has been practical only for the production of impure aluminum alloys, ranging in content from 65–70% aluminum, 25–30% silicon, and 1% or more of iron. Other impurities may include titanium and the carbides and nitrides of aluminum and iron. This impure product may be refined to yield pure aluminum by means of a subsequent distillation process in which the electric-furnace product is dissolved at high temperatures in zinc, magnesium, or mercury baths and then distilled. Aluminum with a purity of 99.99 + % may be produced in this manner.

A gas-reaction purification process also has attracted attention over the years. This is based on aluminum trichloride gas reacting with molten aluminum at about 1000 °C to produce aluminum monochloride gas. Aluminum fluoride gas may be substituted for the aluminum monochloride gas in the process. Raw materials for the process may be scrap aluminum, aluminum from thermal-reduction processes, aluminum carbide, or aluminum nitride. As of the beginning of 1987, none of these other processes are fully commercial.

For the production of superpurity aluminum on a large scale, the Hoopes cell is used. This cell involves three layers of material. Impure (99.35 to 99.9% aluminum) metal from conventional electrolytic cells is alloyed with 33% copper (eutectic composition) which serves as the anode of the cell. A middle, fused-salt layer consists of 60% barium chloride and 40% $AlF_3$1.5NaF (chiolite), mp 720 °C. This layer floats above the aluminum-copper alloy. The top layer consists of superpurity aluminum (99.995%). The final product usually is cast in graphite equipment because iron and other container metals readily dissolve in aluminum. For extreme-purity aluminum, zone refining is used. This process is similar to that used for the production of semiconductor chemicals and yields a product that is 99.9996% aluminum and is available in commercial quantities.

Continuing Research and Development. The industry continues to research improvements in the present production cells. Special attention is being focused on developing inert anodes and cathodes. Ferrites may find use as inert anodes, while titanium diboride may become the optimum material for cathodes. Before commercial use of inert electrodes can be achieved, cell sidewall materials must be developed which will withstand extremely reactive conditions and further improvements (i.e., less solubility of the anode and cathode materials are required). Over the past 15 years, American and Canadian aluminum producers have channeled nearly $1.5 billion into manufacturing technology research, the modernization and computerization of plant facilities, and new and better applications for the metal. Some of the results achieved thus far include:

- Energy efficiency — improved by almost 20%.
- New smelters with large, more efficient electrolytic cells.
- Recycling processes for all types of aluminum scrap, including aluminum beverage cans.
- Electromagnetic casting (EMC) for aluminum ingots in which an electromagnetic force field acts as the mold, thus producing smooth surfaces. In many cases, this eliminates wasteful scalping.
- Fluxing and degassing methods, combined with filtration, to give highest quality aircraft and other critical alloys.
- Continuous casting of filtered molten metal into giant coils (50,000 lb; 22,680 kg) of 0.250-inch (~6.4 mm) strip. This eliminates all hot rolling and intermediate annealing for rolling thin sheet products, such as foil, container stock, siding, etc.
- Aluminum particle rolling directly into continuous strip. Molten metal is sprayed into particles about the size of rice in a controlled environment, then brought to a desired rolling temperature and continuously rolled into "instant" coiled sheet This process can handle alloys which normally cannot be cast in ingot form.
- Computerized-automated cold rolling mills capable of 8000 ft (2438 m) per minute speeds. Multistand cold mills eliminate coil changes and wasted time. See Fig. 4.
- Foil rolling at speeds up to 8000 ft (2438 m) per minute with automatic gauge and shape control.

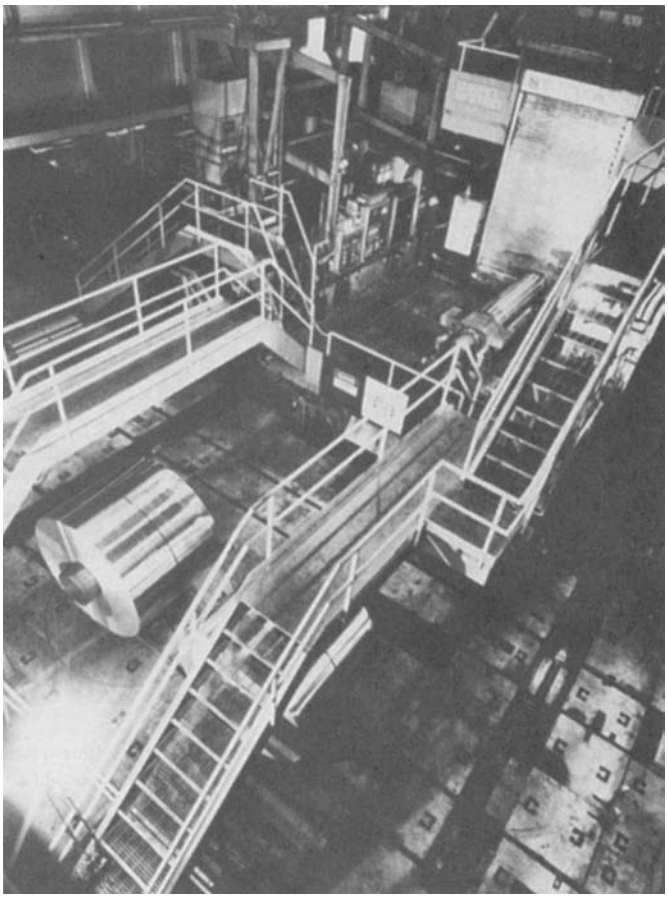

Fig. 4. High-speed, computer-controlled cold rolling mill can roll coils up to 40,000 pounds (18,150 kg), at speeds up to 5500 feet (1675 m) per minute. The system is equipped with automatic hydraulic gage control and shape control systems. (*Reynolds Metals Company*.)

- Aluminum cans have captured over 90% of the beverage industry in the United States. The intent now is to capture a major share of the 30 billion cans food packaging market. (This will be challenged by the increasing use of plastics.)
- Increased use of aluminum in automotive vehicles. Approximately 200 pounds (90 kg) of aluminum per U.S.-built vehicle (i.e., wheels, engine blocks, bumpers, heat exchangers, and other parts).
- New alloys, such as aluminum-lithium alloys for aircraft applications that will permit 7 to 10% weight reduction per aircraft.
- Aluminum powder metallurgy continues to receive high research and development priority. A major objective is to produce final aluminum parts by direct pressing of rapidly solidified aluminum particles. The process handles high-strength aluminum alloy materials.
- Aluminum composites aim at combining high-strength aluminum alloys with alumina ceramic fibers and filaments to provide even higher-strength structural materials.
- Superplastic — high-strength aluminum alloys which can be plastically shaped into difficult designed parts used on cars and aircraft.
- Rheocasting technology for producing stronger castings by combining casting and forging of molten aluminum alloys in one step.
- Ultrasonic welding, used increasingly in the aerospace, automotive, electrical, and electronics industries. The process requires simpler surface preparation and less energy and allows welding of thinner sheets to thicker structural members.
- Inertia (friction) welding in the solid state, which is useful for joining dissimilar metals, i.e., aluminum to steel and stainless steel. At least one of the pieces to be welded must be circular and capable of being rotated at high velocities before being brought into contact with pressure to the second member.
- Vacuum brazing for producing heat exchangers.
- Aluminum as energy (fuel) source. The high energy content of aluminum has made it a logical choice as a sold fuel for boosting vehicles, such as the space shuttle, into orbit.
- Aluminum — air battery. A second potential application of this available energy is based on electrochemical oxidation of aluminum in air to produce electricity. In an aluminum — air battery, for example, thin coils of aluminum strip may be used as the fuel. No electric battery recharging would be required since the aluminum is consumed to generate the electricity directly. This fuel would not give off fumes or pollute and could be stored in solid form indefinitely. If this concept materializes into commercial viability, it will provide the energy needed for electric vehicles.

Some of the foregoing topics are described in more detail in the following article on **Aluminum Alloys and Engineered Materials**.

Aluminum and Space. The year 1986 marked the hundredth anniversary of the Hall-Heroult electrolytic process for producing aluminum economically. Jules Verne, the 19th century fiction writer, foretold the use of aluminum for space travel while it was still a mystery metal. Aluminum is the key metal in the aerospace industry. The Wright brothers recognized its value on their first flight in 1903 by using aluminum to build part of their engine. In military and commercial aircraft, aluminum became the metal of construction as early as 1930 for the U.S. Army P-12 and the Navy F-48, as well as an aluminum dirigible ZNC-2. World War II "light metals war" planes (i.e., B-17, B-25, B-29, etc.) became the forerunners of present aircraft. The U.S. Army Ballistic Missile Agency launched a program in 1950 for surface-to-surface missiles — the Redstone and Jupiter rocket programs. These programs prepared the way for NASA to launch unmanned satellites and to put men on the moon. Aluminum was the metal used for the rockets, the space modules, the moon rover (land vehicle), and most equipment associated with the programs. Today aluminum is used in the solid fuel booster rockets (some containing 0.5 mil lb-0.23 mil kg- of aluminum powder), in the space shuttles and planned space station. Some commercial airliners (jumbo jets 747 and DC-10) contain more than 300,000 lb (~136,000 kg) of aluminum each.

Aluminum Chemistry and Chemicals. Since aluminum has only three electrons in its valence shell, it tends to be an electron acceptor. Its strong tendency to form an octet is shown by the tetrahedral aluminum compounds involving sp^3 hybridization. Aluminum halides include the trifluoride, an ionic crystalline solid, the trichloride and tribromide both of which are dimeric in the vapor and in nonpolar solvents, having the halogen atoms arranged in tetrahedra about each aluminum atom, giving a bridge structure; and the triiodide. They combine readily with many other molecules, especially organic molecules having donor groups, and aluminum chloride is an active catalyst. Certain of the hydrates have a saltlike nature; thus $AlCl_3{\cdot}6H_2O$ acts as a salt, even though Al_2Cl_6 is covalent.

Common water-soluble salts include the sulfate, selenate, nitrate, and perchlorate, all of which are hydrolyzed in aqueous solution. Double salts are formed readily by the sulfate and by the chloride.

There are many fluorocomplexes of aluminum. The general formula for the fluoroaluminates is $M^1_x[Al_yF_{x+3y}]$, based upon AlF_6 octohedra, which may share corners to give other ratios of Al:F than 1:6. Chloroaluminates of the type $M^1[AlCl_4]$ are obtainable from fused melts. Aluminum ions form chloro-, bromo-, and iodo-complexes containing tetrahedral $[AlX_4]^-$ ions. However, in sodium aluminum fluoride $NaAlF_4$, the aluminum atoms are in the centers of octohedra of fluorine atoms in which the fluorine atoms are shared with neighboring aluminum atoms.

Aluminum hydroxide is about equally basic and acidic, the pK_b being about 12 and the pK_a being 12.6. Sodium aluminate seems to ionize as a uni-univalent electrolyte: $NaAl(OH)_4(H_2O)_2 \rightleftharpoons Na^+ + [Al(OH)_4(H_2O)_2]^-$. The high viscosity of sodium aluminate solutions is explained by hydrogen bonding between these hydrated ions, and between them and water molecules. By reaction of aluminum and its chloride or bromide at high temperature, there is evidence of the existence of monovalent aluminum. Here the aluminum atom is apparently in the sp state, with an electron pair on the side away from the chlorine atom, whereby the single pairs on the two chlorine atoms are shared to form two weak π bonds.

Aluminum forms a polymeric solid hydride, $(AlH_3)_x$, unstable above 100 °C, extremely reactive, e.g., giving hydrogen explosively with H_2O and igniting explosively in air. From it are derived the tetrahydroaluminates, containing the ion AlH_4^-, which are important, powerful but selective reducing agents, e.g., reducing chlorophosphines R_2PCl to phosphines R_2PH; reactive alkyl halides and sulfonates to hydrocarbons, epoxides,

and carboxylic acids; aldehydes and ketones to alcohols; nitrites, nitro compounds and N,N-dialkyl amides to amines. The salt most commonly used is lithium (tetra)hydroaluminate ("lithium aluminum hydride").

Aluminum compounds are generally made starting with bauxite, which is reactive with acids and with bases. With acids, e.g., H_2SO_4, any iron contained in the bauxite is dissolved along with the aluminum and silicon is left in the residue, whereas with bases, e.g., NaOH, any silicon is dissolved and iron left in the residue.

Acetate: Aluminum acetate $Al(C_2H_3O_2)_3$, white crystals, soluble, by reaction of aluminum hydroxide and acetic acid and then crystallizing. Used (1) as a mordant in dyeing and printing textiles, (2) in the manufacture of lakes, (3) for fireproofing fabrics, (4) for waterproofing cloth.

Aluminates: Sodium aluminate $NaAlO_2$, white solid, soluble, (1) by reaction of aluminum hydroxide and NaOH solution, (2) by fusion of aluminum oxide and sodium carbonate; the solution of sodium aluminate is reactive with CO_2 to form aluminum hydroxide. Used as a mordant in the textile industry, in the manufacture of artificial zeolites, and in the hardening of building stones. See silicates below and calcium aluminates.

Alundum: See oxide (below).

Carbide: Aluminum carbide Al_4C_3, yellowish-green solid, by reaction of aluminum oxide and carbon in the electric furnace, reacts with H_2O to yield methane gas and aluminum hydroxide.

Chlorides: Aluminum chloride $AlCl_3{\cdot}6H_2O$, white crystals, soluble, by reaction of aluminum hydroxide and HCl, and then crystallizing; anhydrous aluminum chloride $AlCl_3$, white powder, fumes in air, formed by reaction of dry aluminum oxide plus carbon heated with chlorine in a furnace, used as a reagent in petroleum refining and other organic reactions.

Fluoride: Aluminum fluoride AlF_3, white solid, soluble, by reaction of aluminum hydroxide plus hydrofluoric acid and then crystallizing $2AlF_3{\cdot}7H_2O$, used in glass and porcelain ware.

Hydroxide: Aluminum hydroxide $Al(OH)_3$, white gelatinous precipitate, by reaction of soluble aluminum salt solution and an alkali hydroxide, carbonate or sulfide (sodium aluminate is formed with excess NaOH but no reaction with excess NH_4OH), upon heating aluminum hydroxide the residue formed is aluminum oxide. Used as intermediate substance in transforming bauxite into pure aluminum oxide.

Nitrate: Aluminum nitrate $Al(NO_3)_3$, white crystals, soluble, by reaction of aluminum hydroxide and HNO_3, and then crystallizing.

Oleate: Aluminum oleate $Al(C_{18}H_{33}O_2)_3$, yellowish-white powder, by reaction of aluminum hydroxide, suspended in hot H_2O, shaken with oleic acid, and then drying, the product is used (1) as a thickener for lubricating oils, (2) as a drier for paints and varnishes, (3) in waterproofing textiles, paper, leather.

Oxide: Aluminum oxide, alumina Al_2O_3, white solid, insoluble, melting point 2020 °C, formed by heating aluminum hydroxide to decomposition; when bauxite is fused in the electric furnace and then cooled, there results a very hard glass ("alundum"), used as an abrasive (hardness 9 Mohs scale) and heat refractory material. Aluminum oxide is the only oxide that reacts both in H_2O medium and at fusion temperature, to form salts with both acids and alkalis.

Palmitate: Aluminum palmitate $Al(C_{16}H_{31}O_3)_3$, yellowish-white powder, by reaction of aluminum hydroxide, suspended in hot H_2O, shaken with palmitic acid, and then drying, the product is used (1) as a thickener for lubricating oils, (2) as a drier for paints and varnishes, (3) in waterproofing textiles, paper, leather, (4) as a gloss for paper.

Silicates: Many complex aluminosilicates or silicoaluminates are found in nature. Of these, clay in more or less pure form, pure clay, kaolinite, kaolin, china clay $H_4Si_2AlO_2O_9$ or $Al_2O_3{\cdot}2SiO_2{\cdot}2H_2O$ is of great importance. Clay is formed by the weathering of igneous rocks, and is used in the manufacture of bricks, pottery, procelain, and Portland cement.

Stearate: Aluminum stearate $Al(C_{18}H_{35}O_2)_3$, yellowish-white powder, by reaction of aluminum hydroxide suspended in hot H_2O, shaken with stearic acid, and then drying the product, used (1) as a thickener for lubricating oils, (2) as a drier for paints and varnishes, (3) in waterproofing textiles, paper, leather, (4) as a gloss for paper.

Sulfate: Aluminum sulfate $Al_2(SO_4)_3$, white solid, soluble, by reaction of aluminum hydroxide and H_2SO_4, and then crystallizing, used (1) as a clarifying agent in water purification, (2) in baking powders, (3) as a mordant in dyeing, (4) in sizing paper, (5) as a precipitating agent in sewage disposal; aluminum potassium sulfate, see **Alum**; and **Alunite**.

Sulfide: Aluminum sulfide Al_2S_3, white to grayish-black solid, reactive with water to form aluminum hydroxide and H_2S, formed by heating aluminum powder and sulfur to a high temperature.

Aluminum in solution of its salts is detected by the reaction (1) with ammonium salt of aurin tricarboxylic acid ("aluminon"), which yields a red precipitate persisting in NH_4OH solution, (2) with alizarin red S, which yields a bright red precipitate persisting in acetic acid solution.

Organoaluminum Compounds: By the action of alpha olefins on AlH_3, the trialkyls of aluminum can be prepared:

$$AlH_3 + 3\ CH_2 = CHR \xrightarrow{120^\circ} (CH_2CH_2R)_3Al$$

In the presence of ethers, magnesium-alloy alloys react with alkyl halides to yield trialkyls, R_3AlOEt_2. The trimethyl aluminum compound is a dimer, mp 15 °C. Triethyl aluminum is a liquid. The alkyls react readily with H_2O:

$$Et_3Al + 3\ H_2O \longrightarrow Al(OH)_3 + 3\ EtH$$

When aluminum is reacted with diphenyl mercury $(C_6H_5)_2Hg$, triphenylaluminum $(C_6H_5)_3Al$ is yielded. The aluminum organometallic alkyls and aryls act as Lewis acids to form compounds with electron-donating substances. The resulting compounds are the organometallic basis for producing polymers of the Al-N type.

Zeolite Structures: These are crystalline, microporous solids that contain cavities and channels of molecular dimensions (3 Å to 10 Å) and sometimes are called molecular sieves. Zeolites are used principally in catalysis, separation, purification, and ion exchange. The fundamental building block of a zeolite is a tetrahedron of four oxygen atoms surrounding a central silicon atom (i.e., $(SiO_4)^{4-}$). From the fundamental unit, numerous combinations of secondary building units (polygons) can be formed. The corners of these polyhedra may be Si or Al atoms.[2]

Different combinations of the same secondary building unit may yield numerous distinctive zeolites. As pointed out by D.E.W. Vaughan, few fields of chemistry offer such chemical and structural diversity. Although only about sixty structures are known, tens of thousands of theoretical structures are possible. The science of synthesizing zeolites, which achieves much more diversity than is the case with natural zeolites, has been under continuous development for several years. Synthetic zeolites often are cataloged by their Si/Al composition ratios, usually ranging from 1:1 to 10:500. Thus, aluminum plays a large role in this field. In the manufacture of synthetic zeolites, the common reactants are silica from sodium silicate (water-glass) or an aqueous colloidal silica, aluminum from sodium aluminate, alum, or a colloidal alumina (boehmite), and sodium or potassium hydroxide. For further detail, see the Vaughan (1988) reference.

ALUMINUM ALLOYS AND ENGINEERED MATERIALS. Aluminum alloys have been used effectively for scores of years. Much research during the past few decades has been directed not only to expand the list of alloys, but also for applying aluminum in other engineered forms, such as composites, sandwiched, and laminated materials. Aluminum fabrication and surface treatment have been improved. The techniques of powder metallurgy have been expanded to include the new engineering forms of aluminum. Aluminum quasi-crystals are a recent discovery. The "shape memory" of certain aluminum-base materials is being exploited. A process for using shock waves to shape aluminum also is among recent achievements.

Annually, sessions are held on *advanced aluminum alloys* as part of the conference on "Advanced Aerospace Materials/Processes and Exposition." Topics discussed have included rapid-solidification alloys, very low density alloys, laminates, new alloying elements, such as lithium, and such processes as diffusion bonding and means to improve fracture toughness and reduce fatigue and corrosion.

Aluminum is unique among the metals because it responds to nearly all of the known finishing processes. It can be finished in the softest, most delicate textures as exemplified by tableware and jewelry. Aluminum can be anodized and dyed to appear like gold. It can be made as specular as a silver mirror and jet black. The metal also can be anodized to an extremely hard, wear- and abrasion-resistant surface that approaches the hardness of a

[2] Other atoms are used, but to a lesser extent, including Li, Be, B, Mg, Co, Mn, Zn, P, As, Ti, Ga, and Fe.

diamond. Aluminum is available in many convenient forms-shapes, sheet, plate, ingot, wire, rod and bar, foil, castings, forgings, powdered metals, and extrusions.

In the production of these products, new high-speed automated equipment has been developed over the past decade. Rolling speeds as high as 8000 feet (2438 meters) per minute are possible on some products. New continuous casting processes have been developed where molten metal can be converted directly into coiled sheet, using roll casting, belt casting, and articulated block casting. See Figs. 1 and 2. Many of the common alloys respond well to these new processes. Electromagnetic casting of the conventional giant ingots used for the conventional rolling mills has been developed in the fully automated mode. This casting process eliminates the need for scalping ingots prior to processing into final products, such as can stock, foil, auto body sheet, siding, and many other products. In this process, an electrical field rather than a solid mold wall is used to shape the ingot. The process is based upon the fact that liquids with good electrical conductivity, such as aluminum, can be constrained where an alternating magnetic field is applied. The liquid metal remains suspended by the electrical forces while it is being solidified.

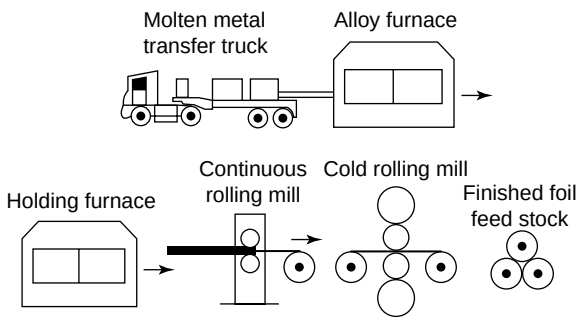

Fig. 1. Schematic portrayal of continuous aluminum roll casting process. (*Reynolds Metals Company*.)

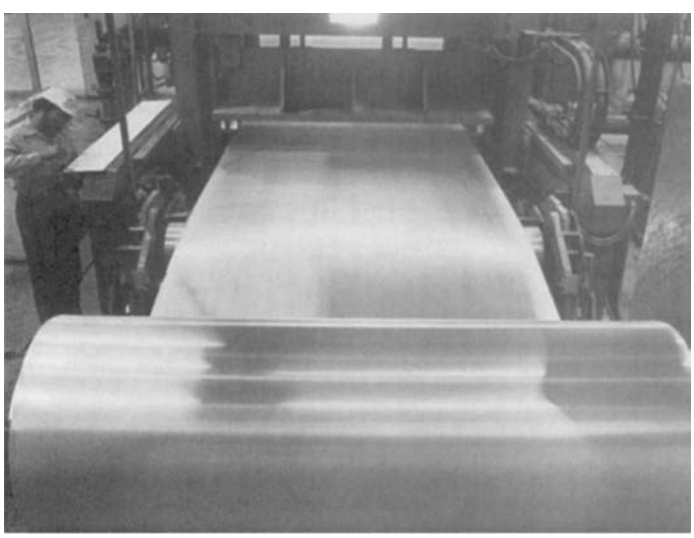

Fig. 2. Continuous rolling plant (Hot Spring, Arkansas) has cast nearly two billion pounds (0.9 billion kg) of aluminum foil feedstock since it began operations in 1979. That quantity of foil would wrap the earth almost 1600 times at the equator. The plant produces coils of feedstock for aluminum foil and flexible packaging products at a 40% energy saving compared to conventional rolling processes. (*Reynolds Metals Company*.)

The casting alloy products comprise sand castings, permanent mold castings, and die castings. Aluminum is the basic raw material for more than 20,000 businesses in the United States. Aluminum is an indispensable metal for aircraft, for example. See Fig. 3. Representative aluminum alloys for a broad classification of uses is given in Table 1.

Worldwide demand for aluminum over the past several decades has increased by approximately 5–6% per year. Aluminum is quite well established as an energy saver and a cost-effective material in numerous applications. Particularly strong growth is occurring in the automotive and transportation fields, housing, and food packaging. For example, a number of breakthroughs in foil pouch packaging have been achieved for replacing conventional cans for shelf-stable foods. Steady growth has continued in other areas, including aircraft and space applications, electrical wire and cable, marine, architectural, and consumer durable products. See Fig. 4.

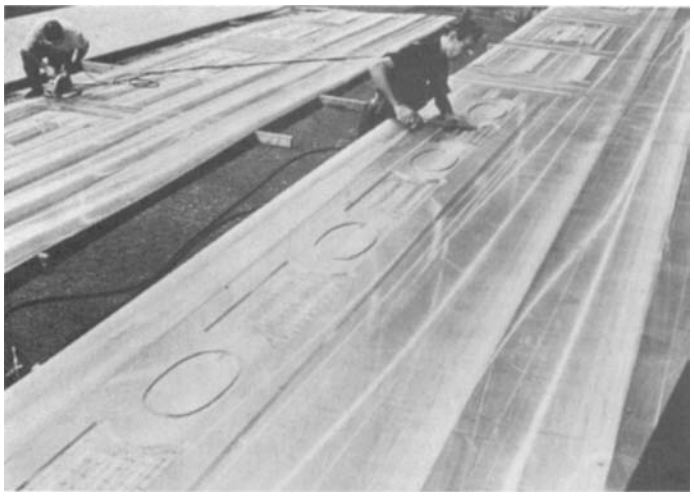

Fig. 3. Final operations on machined aluminum plates for wings of large jet aircraft. (*Reynolds Metals Company*.)

Fig. 4. Four aluminum sections of this type make up fuel tank for aerospace vehicle. Each section is produced from computer-machined plate and weighs 4750 pounds (2155 kg). (*Reynolds Metals Company*.)

Pure aluminum is soft and ductile. In its annealed form, the tensile strength is approximately 13,000 pounds per square inch (90 megapascals). This can be work hardened by rolling, drawing into wire, or by other cold-working techniques to increase its strength to approximately 24,000 pounds per square inch (165 megapascals). Pure aluminum is particularly useful in the food and chemical industries where its resistance to corrosion and high thermal conductivity are desirable characteristics, and in the

electrical industry, where its electrical conductivity of about 62% that of copper and its lightweight make it desirable for wire, cable, and bus bars. Large quantities are rolled to thin foils for the packaging of food products, for collapsible tubes, and for paste and powders used for inks and paints.

Most commercial uses require greater strength than pure aluminum affords. Higher strength is achieved by alloying other metal elements with aluminum and through processing and thermal treatments. The alloys can be classified into two categories, non-heat-treatable and heat-treatable.

Non-Heat-Treatable Alloys. The initial strength of alloys in this group depend upon the hardening effect of elements such as manganese, silicon, iron, and magnesium, singly or in various combinations (see three alloys in Table 2). The non-heat-treatable alloys are usually designated therefore in the 1xxx, 3xxx, 4xxx, and 5xxx series (Table 3). Since these alloys are work hardenable, further strengthening is made possible by various degrees of cold work denoted by the H series tempers.

Heat-Treatable Alloys. This group of alloys includes the alloying elements, copper, magnesium, zinc, and silicon (-T tempered alloys in Table 2). Since these elements singly or in combination show increasing solid solubility in aluminum with increasing temperature, it is possible to subject them to thermal treatments that will impart pronounced strengthening. The first step called heat treatment or solution heat treatment, is an elevated temperature process designed to put the soluble element or elements in solid solution. This is followed by a rapid quenching which momentarily "freezes" the structure and for a short time renders the alloy very workable. At room or elevated temperatures, the alloys are not stable after quenching, and precipitation of the constituent from the supersaturated solid solution begins. After several days at room temperature, termed aging or room temperature precipitation, the alloy is considerably stronger. Many alloys approach a stable condition at room temperature but some alloys, especially those containing magnesium and silicon or magnesium and zinc continue to age harden for long periods of time at room temperature. By heating for a controlled time at slightly elevated temperatures, even further strengthening is possible and the properties are stabilized.

Clad Alloys. The heat-treatable alloys, in which copper or zinc are major alloying constituents, are less resistant to corrosive attack than a majority of the non-heat-treatable alloys. To increase the corrosion resistance of these alloys in sheet and plate form, they are often clad with a high-purity aluminum, a low-magnesium-silicon alloy, or an aluminum alloy containing 1% zinc.

The cladding, usually from $2\frac{1}{2}$ to 5% of the total thickness on each side, not only protects the composite due to its own inherent excellent corrosion

resistance, but also exerts a galvanic effect that further protects the core alloy.

Special composites may be obtained such as clad non-heat-treatable alloys for extra corrosion protection, for brazing purposes, and for special surface finishes.

Composites. The most commonly used metal elements alloyed with aluminum are magnesium, manganese, silicon, copper, zinc, iron, nickel, chromium, titanium, and zirconium. The strength of aluminum can be tailored to the specific end applications ranging from the very soft ductile foils to the high-strength aircraft and space alloys equal to steel in the 90,000 pounds per square inch (621 megapascals) tensile strength range. In addition to the homogeneous aluminum alloys, dispersion hardened and advanced filament-aluminum composites provide even higher strengths. Boron filaments in aluminum can provide strengths in the range of 150,000–300,000 pounds per square inch (1034–2068 megapascals) tensile strength.

Superplasticity. Eutectoid and near eutectoid alloy chemistry research has resulted in alloys exhibiting superplasticity with unusual elongation (>1000%) and formability and with 60,000 pounds per square inch (414 megapascals) tensile strength. Three examples of these alloys are: 94.5% A1-5% Cu-0.5% Zr; 22% A1-78% Zn; and 90% A1, 5% Zn, 5% Ca.

Casting Alloys. During the last two decades, the quality of castings has been improved substantially by the development of new alloys and better liquid-metal treatment and also by improved casting techniques. Casting techniques include sand casting, permanent mold casting, pressure die casting, and others. Today sand castings can be produced in high-strength alloys and are weldable. Die casting permits large production outputs per hour on intricate pieces that can be cast to close dimensional tolerance and have excellent surface finishes; hence, these pieces require minimum machining. Since aluminum is so simple to melt and cast, a large number of foundry shops have been established to supply the many end products made by this method of fabrication. See Table 3.

Al_2O_3, Casting Semisolid Metal. A new casting technology is based on vigorously agitating the molten metal during solidification. A very different metal structure results when this metal is cast. The vigorously agitated liquid-solid mixture behaves as a slurry still sufficiently fluid (thixotropic) to be shaped by casting. The shaping of these metal slurries is termed "Rheocasting."

The slurry nature of "Rheocast" metal permits addition and retention of particulate nonmetal (e.g., Al_2O_3, SiC, T, C, glass beads) materials for cast composites. This new technology is beginning to be commercialized.

Alloy and Temper Designation Systems for Aluminum. The aluminum industry has standardized the designation systems for wrought aluminum alloys, casting alloys and the temper designations applicable. A system of four-digit numerical designations is used to identify wrought aluminum alloys. The first digit indicates the alloy group as shown in Table 4. The 1xxx series is for minimum aluminum purities of 99.00% and greater; the last two of the four digits indicate the minimum aluminum percentage; i.e., 1045 represents 99.45% minimum aluminum, 1100 represents 99.00% minimum aluminum. The 2xxx through 8xxx series group aluminum alloys by major allowing elements. In these series the first digit represents the major alloying element, the second digit indicates alloy modification, while the third and fourth serve only to identify the different alloys in the group. Experimental alloys are prefixed with an X. The prefix is dropped when the alloy is no longer considered experimental.

Cast Aluminum Alloy Designation System. A four-digit number system is used for identifying aluminum alloys used for castings and foundry ingot (see Table 5). In the 1xx.x group for aluminum purity of 99.00% or greater, the second and third digit indicate the minimum aluminum percentage. The last digit to the right of the decimal point indicates the product form: 1xx.0 indicates castings and 1xx.1 indicates ingot. Special control of one or more individual elements other than aluminum is indicated by a serial letter before the numerical designation. The serial letters are assigned in alphabetical sequence starting with A but omitting I, O, Q, and X, the X being reserved for experimental alloys.

In the 2xx.x through 9xx.x alloy groups, the second two of the four digits in the designation have no special significance but serve only to identify the different aluminum alloys in the group. The last digit to the right of the decimal point indicates the product form: .0 indicates casting and .1 indicates ingot. Examples: Alloy 213.0 represents a casting of an aluminum alloy whose major alloying element is copper. Alloy C355.1 represents the third modification of the chemistry of an aluminum alloy ingot whose major alloying elements are silicon, copper, and magnesium.

TABLE 4. DESIGNATIONS FOR CAST ALUMINUM ALLOY GROUPS

		Alloy No.
Aluminium-99.00% minimum and greater		1xxx
	MAJOR ALLOYING ELEMENT	
Aluminium Alloys Grouped by Major Alloying Elements	Copper	2xxx
	Manganese	3xxx
	Silicon	4xxx
	Magnesium	5xxx
	Magnesium and Silicon	6xxx
	Zinc	7xxx
	Other Element	8xxx
Unused Series		9xxx

(1) For codification purposes an alloying element is any element which is intentionally added for any purpose other than grain refinement and for which minimum and maximum limits are specified.

(2) Standard limits for alloying elements and impurities are expressed to the following places:

Less than 1/1000%	0.000X
1/1000 up to 1/100%	0.00X
1/100 up to 1/10%	
Unalloyed aluminum made by a refining process	0.0XX
Alloys and unalloyed aluminum not made by a refining process	0.0X
1/10 through 1/2%	0.XX
Over 1/2%	0.X, X.X, etc.

TABLE 5. DESIGNATIONS FOR CAST ALUMINUM ALLOY GROUPS

		Alloy No.
Aluminum Alloys Grouped By Major Alloying Elements	99.00% minimum and greater	1xx.x
	Major Alloy Element	
	Copper	2xx.x
	Silicon, with added Copper and/or Magnesium	3xx.x
	Silicon	4xx.x
	Magnesium	5xx.x
	Zinc	7xx.x
	Tin	8xx.x
	Other Element	9xx.x
Unused Series		6xx.x

(1) For codification purposes an alloying element is any element which is intentionally added for any purpose other than grain refinement and for which minimum and maximum limits are specified.

(2) Standard limits for alloying elements and impurities are expressed to the following places:

Less than 1/1000%	0.000X
1/1000 up to 1/100%	0.00X
1/100 up to 1/10%	
Unalloyed aluminum made by a refining process	0.0XX
Alloys and unalloyed aluminum not made by a refining process	0.0X
1/10 through 1/2%	0.XX
Over 1/2%	0.X, X.X, etc.

Temper Designation System. A temper designation is used for all forms of wrought and cast aluminum alloys. The temper designation follows the alloy designation, the two letters being separated by a hyphen. Basic designations consist of letters followed by one or more digits. These designate specific sequences of basic treatments but only operations recognized as significantly influencing the characteristics of the product. Basic tempers are -F (as fabricated), -O annealed (wrought products only), -H strain-hardened (degree of hardness is normally quarter hard, half hard, three-quarters hard, and hard, designated by the symbols H12, H14, H16, and H18, respectively). -W solution heat-treated and -T thermally treated to produce stable tempers. Examples: 1100-H14 represents commercially pure aluminum cold rolled to half-hard properties. 2024-T6 represents an aluminum alloy whose principal major element is copper that has been

solution heat treated and then artificially aged to develop stable full-strength properties of the alloy.

Contemporary Advancements and Future Potential

Highlighted in the following paragraphs are improvements in aluminum metallurgy that have occurred and have been available only relatively recently or that are promising but that still remain in a late phase of research or testing.

Aluminum-Lithium Alloys. Both private and government funding have been invested in Al-Li alloy research for several years. As of the early 1990s, exceptionally good results had been achieved by way of increasing the strength-to-weight ratio and the stiffness of Al-Li alloys. Low ductility in the short-transverse direction has been a difficult problem to solve. Wide usage awaits further problem solving and testing for critical applications. The Al-Li alloy 2091-T3 (Pechiney) is a medium-strength, lightweight alloy quite similar to the traditional alloy 2024-T3, which it is expected to replace for aerospace applications. The new alloy has a 7% lower density and a 10% higher stiffness. The new alloy, like most Al alloys, is notch sensitive. An oxide film composed of MgO, LiO_2, $LiAlO_2$, Li_2CO_3, and LiOH tends to develop under normal production conditions. Cracks form in this film and tend to initiate cracks in the alloy's substrate and this reduces fatigue life. When the film is removed, in both longitudinal and long-transverse directions, the new alloy's fatigue properties are comparable with other aluminum alloys.

In late 1989, the availability of a proprietary family of weldable, high-strength (*Weldalite*) Al-Li products appeared. The material was claimed to be nearly twice as strong (100×10^3 psi) as other leading alloys then currently used for aerospace applications. The alloy was initially developed especially for space-launch systems. Specific advantages claimed include: (1) high strength over a broad temperature range, from cryogenic to highly elevated temperatures, (2) light weight, and (3) weldability — this property being of particular value for fabricating fuel and oxidizer tanks for space vehicles. *Weldalite* is produced in sheet, plate, extrusion, and ingot products.

Al-Li investment castings are gaining acceptance. Among aluminum alloying elements, lithium is one of the most soluble. About 4.2% Li can be dissolved in Al at the eutectic temperature, 1116 °F (602 °C). However, in commercial-size ingots, the maximum Li content that can be cast without cracking is about 2.7%. Lithium is a strengthening element because of the formation of small, coherent ordered Al3Li precipitates during aging (secondary hardening when Li content exceeds 1.4%). The toughness of Al-Li alloys, unlike conventional Al alloys, does not increase with increasing aging temperature (beyond that point needed for peak strength).

Metal-Matrix Composites. Silicon carbide particles are contributing to easy-to-cast metal-matrix composites (MMCs). When compared with their non-reinforced counterparts, the SiCp/Al components are more wear resistant, stiffer, and stronger, accompanied by improved thermal stability. Additional advantages include lower density and lower cost. Nearly all prior aluminum MMCs required labor-intensive methods, such as powder metallurgy, diffusion bonding, squeeze casting, or thermal spraying.

The new SiC composites are available as foundry ingot or extrusion billets. A new process ensures complete wetting of the SiC particles by molten aluminum. A number of investment castings are now being made, including aircraft hydraulic components and other small parts. These composites have excellent prospects for use in a variety of small parts, including medical prostheses and golf club heads.

Sialons consist of three-dimensional arrays of (Si-Al) $(O,N)_4$ tetrahedra. These oxynitrides are traditionally fabricated with silicon nitride. An example is beta-sialon, where the O and Si are partially replaced by N and Al, respectively. Advanced sialons are now being researched to enhance fracture toughness and improved creep properties.

Aluminides. These are intermetallic compounds of aluminum. The potential of these products includes uses where low weight, high-temperature strength, and oxidation resistance are required. Traditionally, these products are made by way of powder metallurgy technology. Powder consolidation has been affected by sintering and hot isostatic pressing, both methods requiring long processing at height temperature. They rely mainly on solid-state diffusion. In a more recent method, *dynamic consolidation* uses high-pressure shock waves traveling at several kilometers per second. Such shocks can be generated through the use of detonating explosives or a gun-fired projectile. Upon full development of the shock-wave technique, advantages predicted include: (1) the non-equilibrium microstructures produced in rapid-solidification processing of powders will be retained in the final compact, (2) composite materials may be fabricated with very thin reaction zones between matrix and reinforcement, thus minimizing brittle reaction products that distract from the composite properties, and (3) net shapes may be produced. Normally confined in the past to production of centimeter-size parts, an improved process may be scaled up to meter-size products. Further development is required to prevent the formation of cracks.

Shape-Memory Alloys. Stoeckel defines a shape-memory alloy as the ability of some plastically deformed metals (and plastics) to resume their original shape upon heating. This effect has been observed in numerous metal alloys, notably the Ni-Ti and copper-based alloys, where commercial utilization of this effect has been exploited. (An example is valve springs that respond automatically to change in transmission-fluid temperature.) Copper-based alloy systems also exhibit this effect. These have been Cu-Zn-Al and Cu-Al-Ni systems. In fact, the first thermal actuator to utilize this effect (a greenhouse window opener) uses a Cu-Zn-Al spring.

ARALL Laminates. Developed in the late 1970s, *AR*amid *AL*uminum *L*aminates were developed by Delft University and Fokker Aircraft Co. The laminate currently is used for the skin of the cargo door for the Douglas C-17 military transport aircraft, but additional aerospace applications are envisioned. In essence, the laminate comprises a prepreg (i.e., unidirectional aramid fibers embedded in a structural epoxy adhesive) sandwiched between layers of aircraft alluminum alloy sheet. The fibers are oriented parallel to the rolling direction of the aluminum sheet. Prior to lay-up and autoclave curing, the aluminum surfaces are anodized and primed to ensure good bond integrity and to inhibit corrosion of the metal in the event of moisture intrusion at the bond line.

Quasicrystals. In the early 1980s, D. Schechtman at NIST (U.S. National Institute for Standards and Technology) discovered quasicrystals in aluminum alloys. Since then, they also have been noted in other alloys, including those of copper, magnesium, and zinc. Quasicrystals contradict the traditional fundamentals of crystallography to the effect that the periodicity of a perfect crystal structure is not possible with pentagon shapes. Much pioneering research on quasicrystals also has been conducted at the Laboratoire de Science at Génie des Matériaux Métalliques in France.

To date, little use has been found for quasicrystals in bulk, but they have proved very effective as coatings, notably in cookware. Recent cookware, with a different appearance and "feel," has appeared in the marketplace. These pots, pans, and so on, have a hardness equal to that of hardened alloy steel and thus are practically immune to scratching. They also are thermally stable and corrosion and oxidation resistant.

The coating is applied by using flame, supersonic, and plasma-arc spraying. The deposited material consists of a mixture of quasicrystals and crystalline phases. The quasicrystal content of the surface ranges from 30–70%.

In structure, the quasicrystal relates to the Penrose tile structures (polygon), originally proposed by Roger Penrose, a mathematician at Oxford University. See **Crystal**.

Advances in Powdered Metallurgy (PM) Aluminum Alloys. As noted by Frazier, materials for advanced airframe structures and propulsion systems must withstand increasingly high temperature exposure. For example, frictional heating can raise supersonic skin temperatures to a range of 555° to 625 °F (290° to 330 °C). Unfortunately, wrought age-hardening aluminum alloys lose strength above 265 °F (130 °C). Titanium alloys perform well under these conditions, but they are 67% denser than aluminum, constituting about 42% of the weight of contemporary turbofan engines. Replacement of half the titanium with aluminum would reduce engine weight by about 20%. The motivation for using PM products is cost reduction and improved performance. Advanced thermoplastic matrix composites under development are difficult to process and presently cost prohibitive. Thus, intensive research is underway to improve rapid solidification technology and other new PM processes to increase the alloy aluminum content, thus reducing weight and cost.

Aluminum Electroplating. Electroplated aluminum is growing in acceptance for use in automotive parts, electrical equipment, and appliances and for products in a marine environment. Markets may be extended as the result of a new galvano-aluminum electroplating process developed by Siemens Research Laboratory (Erlangen, Germany) and described in the Hans reference.

ALUNITE. The mineral alunite, $KAl_3(SO_4)_2(OH)_6$, is a basic hydrous sulfate of aluminum and potassium; a variety called natroalunite is rich in soda. Alunite crystallizes in the hexagonal system and forms rhombohedrons with small angles, hence resembling cubes. It may be in fibrous or tabular forms, or massive. Hardness, 3.5–4; sp gr, 2.58–2.75; luster, vitreous to pearly; streak white; transparent to opaque; brittle; color, white to grayish or reddish.

Alunite is commonly associated with acid lava due to sulfuric vapors often present; it may occur around fumaroles or be associated with sulfide ore bodies. It has been used as a source of potash. Alunite is found in the Czech Republic and Slovakia, Italy, France, and Mexico; in the United States, in Colorado, Nevada, and Utah.

Alunite is also known as *alumstone*.

ALVEOLUS. See **Respiratory System**.

ALZHEIMER'S DISEASE AND OTHER DEMENTIAS. A progressive, neurodegenerative disease characterized by loss of function and death of nerve cells in several areas of the brain, leading to loss of mental functions such as memory and learning. Alzheimer's disease is the most common cause of dementia. Today, dementia is most commonly associated with Alzheimer's disease (AD), although there are other neurological disorders that cause dementia. The latter are described briefly towards the end of this article.

Only within the relatively recent past has AD gained formal medical recognition and prominence. It does seem reasonable, however, to assume that AD has been a major cause of dementia, particularly among the elderly, for a long time, possibly dating back to the dawn of humankind. Little research has been directed toward fixing the origin or present demographics of the disease, with the exception of a report prepared by a Dr. Alois Alzheimer (Germany) in 1907 concerning the symptoms of the disease. This report will be described a bit later in this article.

Although cognitive decline in advanced age has been recognized throughout history, the understanding that it represents the result of specific disease states is more recent. Longer life spans and increasing knowledge of the causes of cognitive decline, particularly Alzheimer's disease, has led to the prediction of dementia as an epidemic extending into the 21st century. The cost of caring for patients with dementia is already immense, approximately $100 billion annually in the US. The number of AD cases is expected to triple to nearly 15 million over the next 50 years.

The period from first detection of AD to termination ranges from a few years up to 15 years or more, during which time the patient requires progressively increasing care. Ultimately, there is total loss of mental function and control of bodily functions, representing great family anguish and high medical costs.

As with other diseases, AD can be defined in terms of (1) symptoms, and (2) the biological processes that bring about the disease. Considering the present state of AD research, the actual cause (etiology) of the disease cannot be stated definitively. Present AD research is directed toward determining the cause. However, the end condition (at death of patient) can be determined by an autopsy of the brain. To date, only limited success has been achieved by using noninvasive instrumental means, such as the CAT scan, to learn of the progress of the disease in the living patient.

AD Symptoms. It is interesting to note that, in retrospect, a report prepared by Alois Alzheimer in 1907 rather accurately described the symptoms of an AD patient in his care. His description of the unnamed disease at that time was of little significance for nearly a century. In his report, typical AD symptoms were described and included:

1. Unexplainable alteration of personality, including fits of jealousy, fear of the unknown, and fear of being harmed or murdered;
2. Outbursts of imagined terror;
3. Random but progressively occurring periods of forgetfulness;
4. Seriously erratic behavior, such as moving household objects about and sometimes hiding them for no particular reason; and
5. Getting "lost" in one's own household, not knowing the time of day, and like factors.

Some of these patterns, of course, are present in other mental illnesses, and all are not apparent in any given AD patient.

Clinical Manifestations

The primary cognitive feature of AD is usually progressive memory impairment. The memory dysfunction involves impairment of learning new information, which is often characterized as short-term memory loss. In the early (mild) and moderate stages of the illness, recall of remote well-learned material may appear to be preserved, but new information cannot be adequately incorporated into memory. Disorientation to time is closely related to memory disturbance.

Language impairments are also a prominent part of AD. These are often manifest first as word finding difficulty in spontaneous speech. The language of the AD patient is often vague, lacking in specifics and may have increased automatic phrases and cliches. Difficulty in naming everyday objects is often prominent. Complex deficits in visual function are present in many AD patients, as are other focal cognitive deficits such as apraxia, acalculia and left-right disorientation. Impairments of judgement and problems solving are frequently seen.

Non-cognitive or behavioral symptoms are common in AD and may account for an event larger proportion of caregiver burden or stress than the cognitive dysfunction. Personality changes are commonly reported and range from progressive passivity to marked agitation. Patients may exhibit changes such as decreased expressions of affection. In some cases, personality changes may predate cognitive abnormality. Depressive symptoms are present in up to 40%. A similar rate for anxiety has also been recognized. Psychosis occurs in 25%.

Differential Diagnosis

In order to bring uniformity to the diagnosis of such diverse symptoms, a joint National Institute of Health (NIH)/Alzheimer's Association working group (NINCDS-ADRDA) developed criteria for the clinical diagnosis of probable and possible AD. Of the patients diagnosed with probable AD using these criteria, the diagnosis is confirmed at autopsy 85-90%. In brief, the criteria require a one-year course of decline in two or more areas of cognition such as memory, language, visuospatial function, orientation, judgement and problem solving. Neurologic exam should be otherwise normal.

Pick's disease (now know as Frontal Type Dementia) is characterized by prominent behavioral disturbances, with relatively preserved cognition. Evidence of significant vascular disease can be found in as many as one-third of cases, of dementia. A history of hypertension, stroke or clear-cut transient ischemic attacks and the presence of localizing signs on neurologic exam makes a vascular contribution to the dementia very likely. Other common dementias, have prominent motor signs at presentation and have been called "subcortical dementias." These include a wide variety of Parkinson-like motor presentations accompanied by fluctuating cognitive abilities and, frequently, hallucinations. Normal pressure hydrocephalus is often raised as a possibility on radiologic studies. It should only be seriously considered when the dementia is mild and follows a more severe gait disturbance. Incontinence is variable.

Diagnostic Testing

The clinical approach to the patient presenting with memory problems is based on the identification of the specific cognitive changes noted in the NINCDS-ADRDA criteria. This involves physical and neurological examination accompanied by cognitive testing to identify the characteristic memory, language and other cognitive and non-cognitive symptoms. Mental status testing should include remembering three unrelated words, naming parts of common objects (lab coat: lapel, pocket, sleeve, cuff) and the clock-drawing test. The neurologic exam should focus on identifying localizing signs and Parkinsonism.

The screening for illness states, which may mimic AD involves laboratory testing with particular emphasis on thyroid function, vitamin B12 levels and inflammatory or infectious states such as neurosyphilis or HIV. Head CT or MRI are useful to exclude structural lesions which may contribute to the dementia such as cerebral infarctions, neoplasm, extracerebral fluid collections and hydrocephalus. No currently available ante-mortem tests can provide definitive diagnosis despite the commercial availability of genetic and spinal fluid markers and neuroimaging.

Prognosis/Complications

The average survival for patients diagnosed with probable Alzheimer's disease is about eight years, though the range is quite wide and may extend in excess of 15 years. Younger onset patients may have somewhat more aggressive courses, with prominent language and visuospatial problems. Those individuals with onset in their eighties often have primarily memory loss and a more gradual decline.

Delirium or acute confusion is a common complication of dementia even with fairly mild metabolic derangements.

Management

The management of dementia is complex; ideally, it involves an interdisciplinary approach to assessment, treatment and education. The roles of nursing, social work, psychology and case management can be vital to the effective longitudinal care of the patient with AD. The impact of a multidisciplinary treatment approach can be much greater than any medical or pharmacologic intervention in isolation. An important resource to draw upon is the Alzheimer's Association.

Non-pharmacologic management of patients is desirable whenever possible. Increased socialization, such as through day-care programs and improved sleep hygiene may minimize the need for pharmacologic intervention for many difficult behaviors. Acute changes in behavior suggest a complicating factor such as infection or metabolic disturbance. A major goal of the overall treatment plan should be the prevention of excess disability. This can be achieved by minimizing adverse drug effects and by maximizing caregiver skills and knowledge.

Pharmacologic approached include cognitive enhancers, such as tacrine (Cognex) and donepezil (Aricept). These cholinesterase inhibitors have been shown to improve cognition and delay functional decline in AD. Their use has been associated with reduced cost of illness and delayed nursing home placement. SSRI antidepressants are useful in managing depression and anxiety. Low doses of antipsychotic drugs (e.g. haloperidol 0.5 mg qd-bid) are useful in mild delusional states as well as more nonspecific agitation. Acute acting anxiolytics such as lorazepam are best reserved for patients with clear episodic anxiety, since they can increase confusion. Recently, clinical trials have suggested that antioxidants such as Vitamin E may slow the progression of AD. Other disease modifying agents such as estrogen and anti-inflammatory drugs are also in trials.

Warning Signs

To help you know what warning signs to look for, the Alzheimer's Association has developed a checklist of common symptoms (some of them may apply to other dementing illnesses).

- *Recent Memory Loss that Affects Job Skills*. It is normal to occasionally forget assignments, colleagues' names, or a business associates telephone number and remember them later. Those with a dementia, such as Alzheimer's disease, may forget things more often and not remember them later.
- *Difficulty Performing Familiar Tasks*. Busy people can be so distracted from time to time that they may leave the carrots on the stove and only remember to serve them at the end of the meal. People with Alzheimer's disease could prepare a meal and not only forget to serve it, but also forget they made it.
- *Problems with Language*. Everyone has trouble finding the right word sometimes, but a person with Alzheimer's disease may forget simple words or substitute inappropriate words, making his or her sentence incomprehensible.
- *Disorientation of Time and Place.* It is normal to forget the day of the week or you destination for a moment. But people with Alzheimer's disease can become lost on their own street, not knowing where they are, how they got there or how to get back home.
- *Poor or Decreased Judgement*. People can become so immersed in an activity that they temporarily forget the child they are watching. People with Alzheimer's disease could entirely forget the child under their care. They may also dress inappropriately, wearing several shirts or blouses.
- *Problems with Abstract Thinking*. Balancing a checkbook may be disconcerting when the task is more complicated than usual. Someone with Alzheimer's disease could forget completely what the numbers are and what needs to be done with them.
- *Misplacing Things*. Anyone can temporarily misplace a wallet or keys. A person with Alzheimer's disease may put things in inappropriate places: an iron in the freezer, or a wristwatch in the sugar bowl.
- *Changes in Mood or Behavior*. Everyone becomes sad or moody from time to time. Someone with Alzheimer's disease can exhibit rapid mood swings from calm tears to anger for no apparent reason.
- *Changes in Personality*. People's personalities ordinarily change somewhat with age. But a person with Alzheimer's disease can change drastically, becoming extremely confused, suspicious or fearful.
- *Loss of Initiative*. It is normal to tire of housework, business activities, or social obligations, but most people regain their initiative. The person with Alzheimer's disease may become very passive and require cues and prompting to become involved.

AD Biological Process(es). What does the examiner find when an autopsy of the brain is conducted?

1. The brain of an AD patient may be smaller and of a coarser appearance. (See Fig. 1.)
2. Plaques of the brain protein (beta amyloid) that are surrounded by neurons, the latter featuring neurofibrillary tangles.
3. A loss of neuronal cells.
4. Vascular damage resulting from the deposition of plaque.

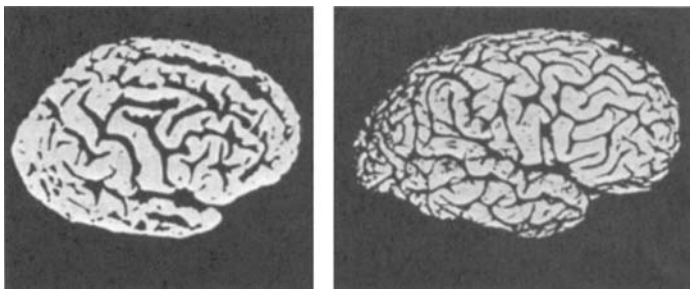

Fig. 1. Brain comparison: (*Left*) Brain from an Alzheimer's disease patient; (*Right*) Normal brain. (*Laboratory of Neuroscience, National Institute of Aging.*)

A more technically worded definition is contained in the Murrell, et al. (1991) article: "Alzheimer's disease is a form of localized amyloidosis characterized by cerebral cortical amyloid plaques, neurofibrillary tangles, and amyloid deposits within the walls of leptomeningeal vessels."

Avenues of Research. A clear-cut tie of a specific gene mutant that can be passed along to family progeny would, as with a few genetic diseases researched thus far, would have provided (perhaps) a relatively fast answer to AD research. It has been found that with some AD patients a familial manifestation of the disease occurs, and research along these lines is being conducted, as indicated by the Murrell, et al. (1991) article previously mentioned. But hereditary or familial AD represents only some of the cases. Research to date indicates that a majority of AD cases are *sporadic* (non-familial).

The key research target of many AD research groups has centered on the protein beta-amyloid, its precursor (APP), and related chemistry, including degenerative products. Nerve growth factor also has been a target.

Because of the inability to observe the progress of AD in living patients, a number of researchers have developed transgenic animals (mouse and rat) that will exhibit Alzheimer's-like pathology. After claiming success in this area in 1991, some researchers have more recently expressed disappointment with the animal models developed.

Researchers to date have not found the fundamental key(s) to AD, and the prospects of solving this complex riddle do not appear to lie within a short time frame. Forecasts for finding the fundamental causation (or multiple factors) range from mildly pessimistic to mildly optimistic. Meanwhile, AD research is enriching the scientific knowledge on the higher functions of the brain, which is the target of Alzheimer's disease.

Arteriosclerotic Dementia

In *arteriosclerotic dementia*, many of the symptoms of which parallel those of Alzheimer's disease, the cause of the condition is well known, namely, a reduced cerebral blood flow. In Alzheimer's disease, the blood flow is normal. Arteriosclerotic dementia is sometimes called *multi-infarct dementia* because of atherosclerosis of small arteries and patchy cerebral infarction. The onset of this condition may be abrupt.

Occult Hydrocephalus

In the syndrome of *occult hydrocephalus*, where there is normal cerebrospinal fluid pressure, some researchers have found that this form of dementia may be reversible as the result of shunting. At one time, it was believed that shunting may improve Alzheimer's disease, but this has not proven so. However, it is difficult for neurosurgeons to discern situations where shunting may or may not be useful. Some neurologists prefer to use the shunt procedure only in cases where there has been a known episode of meningitis, trauma, or sub-arachnoid hemorrhage.

AMALGAM. 1. An alloy containing mercury. Amalgams are formed by dissolving other metals in mercury, when combination takes place often with considerable evolution of heat. Amalgams are regarded as compounds of mercury with other metals, or as solutions of such compounds in mercury. It has been demonstrated that products which contain mercury and another metal in atomic proportions may be separated from amalgams. The most commonly encountered amalgams are those of gold and silver. See also **Gold**; **Mercury**; and **Silver**.

2. A naturally occurring alloy of silver with mercury, also referred to as mercurian silver, silver amalgam, and argental mercury. The natural amalgam crystallizes in the isometric system; hardness, 3–3.5; sp gr, 13.75–14.1; luster, metallic; color, silver-white; streak, silver-white; opaque. Amalgam is found in Bavaria, British Columbia, Chile, the Czech Republic and Slovakia, France, Norway, and Spain. In some areas, it is found in the oxidation zone of silver deposits and as scattered grains in cinnabar ores.

AMARANTHUS. Genus of plants in the family *Amaranthaceae* (amaranth family), including many coarse and rather obnoxious pigweeds. *Amaranthus caudatus*, the love-lies-bleeding; and the *A. hypochondriacus*, the Princess feather are cultivated in gardens for their attractive green, purple, and crimson flowers. They are annuals.

AMBER. Amber is a fossil resin known since early times because of its property of acquiring an electric charge when rubbed. In modern times it has been used largely in the making of beads, cigarette holders, and trinkets. Its amorphous non-brittle nature permits it to be carved easily and to acquire a very smooth and attractive surface. Amber is soluble in various organic solvents, such as ethyl alcohol and ethyl ether.

It occurs in irregular masses showing a conchoidal fracture. Hardness, 2.25; sp gr, 1.09; luster, resinous; color, yellow to reddish or brownish; it may be cloudy. Some varieties will exhibit fluorescence. Amber is transparent to translucent, melts between 250 and 300 °C.

Amber has been obtained for over 2,000 years from the lignite-bearing Tertiary sandstones on the coast of the Baltic Sea from Gdansk to Liepája; also from Denmark, Sweden and the other Baltic countries. Sicily furnishes a brownish-red amber that is fluorescent.

The association of amber with lignite or other fossil woods, as well as the beautifully preserved insects that are occasionally in it, is ample proof of its organic origin.

AMBERGRIS. A fragrant waxy substance formed in the intestine of the sperm whale and sometimes found floating in the sea. It has been used in the manufacture of perfumes to increase the persistence of the scent. See also **Whales, Dolphins, and Porpoises**.

AMBIENT AIR. 1. Background, environmental, or surrounding air. When studying the dynamic and thermodynamic processes acting on an individual element such as an air parcel, cloud, smoke plume, raindrop, or ice crystal, ambient air represents the atmosphere outside of that element. The ambient air is often assumed to be static and of relatively large domain, within which the element resides.

2. The air that surrounds us, within which we live. When air pollutants of high concentration from exhaust or stack gases are emitted into cleaner air, the resulting polluted mixture is called the ambient air. National Ambient Air Quality Standards (NAAQS), apply to this final mixture, not to the undiluted emission gases.

National Ambient Air Quality Standards (NAAQS)

The Clean Air Act, which was last amended in 1990, requires EPA to set National Ambient Air Quality Standards (40 CFR part 50) for pollutants considered harmful to public health and the environment. The Clean Air Act established two types of national air quality standards. ***Primary standards*** set limits to protect public health, including the health of "sensitive" populations such as asthmatics, children, and the elderly. ***Secondary standards*** set limits to protect public welfare, including protection against decreased visibility, damage to animals, crops, vegetation, and buildings.

The EPA Office of Air Quality Planning and Standards (OAQPS) has set National Ambient Air Quality Standards for six principal pollutants, which are called *criteria pollutants*. They are listed in Table 1. Units of measure for the standards are parts per million (ppm) by volume, milligrams per cubic meter of air (mg/m^3), and micrograms per cubic meter of air ($\mu g/m^3$).

AMBIENT CONDITIONS. These are the conditions of environment in which an instrument or device operates. As various environmental factors change, they may seriously alter the accuracy and other performance parameters of equipment. The effects of ambient changes may be combatted in two basic ways: (1) *ambient compensation*, in which a technique is used to offset the effects of environmental changes, such as changes in

TABLE 1. NATIONAL AMBIENT AIR QUALITY STANDARDS

Pollutant	Primary Stds.	Averaging Times	Secondary Stds.
Carbon Monoxide	9 ppm ($10\ mg/m^3$)	8-hour[a]	None
	35 ppm ($40\ mg/m^3$)	1-hour[a]	None
Lead	$1.5\ \mu g/m^3$	Quarterly Average	Same as Primary
Nitrogen Dioxide	0.053 ppm ($100\ \mu g/m^3$)	Annual (Arithmetic Mean)	Same as Primary
Particulate Matter (PM_{10})	Revoked(2)	Annual[b] (Arith. Mean)	
	$150\ \mu g/m^3$	24-hour[c]	
Particulate Matter ($PM_{2.5}$)	$15.0\ \mu g/m^3$	Annual[d] (Arith. Mean)	Same as Primary
	$35\ \mu g/m^3$	24-hour[e]	
Ozone	0.08 ppm	8-hour[f]	Same as Primary
	0.12 ppm	1-hour[g] (Applies only in limited areas)	Same as Primary
Sulfur Oxides	0.03 ppm	Annual (Arith. Mean)	—
	0.14 ppm	24-hour[a]	—
	—	3-hour[a]	0.5 ppm ($1300\ \mu g/m^3$)

[a] Not to be exceeded more than once per year.
[b] Due to a lack of evidence linking health problems to long-term exposure to coarse particle pollution, the agency revoked the annual PM_{10} standard in 2006 (effective December 17, 2006).
[c] Not to be exceeded more than once per year on average over 3 years.
[d] To attain this standard, the 3-year average of the weighted annual mean $PM_{2.5}$ concentrations from single or multiple community-oriented monitors must not exceed $15.0\ \mu g/m^3$.
[e] To attain this standard, the 3-year average of the 98th percentile of 24-hour concentrations at each population-oriented monitor within an area must not exceed $35\ \mu g/m^3$ (effective December 17, 2006).
[f] To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.
[g] (a) The standard is attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is ≤ 1, as determined by appendix H.
(b) As of June 15, 2005 EPA revoked the 1-hour ozone standard, http://www.epa.gov/oar/oaqps/greenbk/oindex.html, in all areas except the fourteen 8-hour ozone nonattainment Early Action Compact (EAC) Areas, http://www.epa.gov/air/eac/.

temperature; pressure; supply voltage, frequency, and waveform; shock and vibration; and position, and (2) *ambient protection*, in which the equipment is protected from its environment, that is, by way of isolation, insulation, and similar techniques. When procuring instruments and other sensitive laboratory and research equipment, the expected range of ambient conditions over which the equipment will be used always should be specified, and the manufacturer's assurance of ambient compensation and/or protection should be studied carefully.

Ambient Compensation. An electrical circuit may be made relatively insensitive to temperature changes by use of components, such as *manganin* or *evanohm* wire for resistors. The resistances of these alloys are only slightly affected by temperature changes in the range of laboratory and industrial environments. Mechanical means of offsetting temperature changes include bimetals or other combinations of materials with different temperature coefficients of expansion. Where stability of dimensions must be maintained, materials with very low thermal expansion coefficients, such as *invar*, may be used in construction of the equipment.

The spring rate of a pressure-sensitive element, such as a bourdon tube, will be affected by temperature change. For most materials, the modulus of elasticity will decrease with increasing temperature, thereby causing an incorrect higher indication. Use of a bimetal to reduce the span is one common means for correcting this effect. Making the pressure element of *Ni-span C*, which has an essentially constant modulus, is another way of correcting the condition.

Manual temperature correction means are provided on several instruments, such as mercurial barometers and precision manometers. Volume changes in a fluid-filled device caused by temperature variations may be offset by a pressure-sensitive diaphragm, which is deflected by expansion of the fluid to maintain a relatively constant pressure. A similar principle is used in the hydraulic accumulator.

To prevent a pressure-sensitive element from being affected by ambient pressure changes, the element may be hermetically sealed within a rigid enclosure.

Correction curves and tables also are widely used. The output of the uncompensated instrument is read, the ambient conditions noted, and the proper correction found in a table. This technique is less convenient than automatic or even manual compensation. However, under reasonably stable environmental influences, the method may be more accurate and practical than automatic compensation.

Instruments are usually designed to tolerate some variation in supply voltage. The availability of zener diodes in a wide range of voltage ratings simplifies the problem of maintaining dc voltage levels with almost any required degree of exactness. Power supplies with ac line input and dc output are available commercially with almost any desired combination of voltage, current, range of adjustability, line and load regulation, ambient temperature compensation, ripple, transient suppression, and package configuration. Alternating current voltage regulators can be obtained to maintain constant output within the needed tolerance for input variations of any likely magnitude, with widely differing speeds of response and power capabilities. The quality of the output waveforms differs markedly, depending upon the operating principle and the magnitude and nature of the load. Care always must be exercised in determining the quality of waveform needed to assure satisfactory operation of the equipment being powered. See also **Power Sources and Supplies**.

The accuracy and stability of line power frequency normally are adequate for most applications. Short-term frequency variations seldom are more than a fraction of a hertz on a 50- or 60-Hz line. Where exceptionally close regulation of frequency is needed, as in the case of very accurate timing, an electronic oscillator may be built into the equipment.

Ambient Protection. Ambient condition protection may be used to isolate the instrument or device from the undesirable environment. The dividing line between this approach and that of ambient compensation is narrow and sometimes difficult to define.

Cleanliness of environment, such as air or liquid as an input to equipment, is an ambient condition difficult to measure, but often necessary for satisfactory long-term operation. Where gases and liquids are involved, it may be necessary to remove solid particles by mechanical filtering, washing, or centrifuging; moisture may have to be removed by cooling and condensing, by the use of desiccants, or by centrifuging; oil may have to be removed by chemical absorption or mechanical filtering. These problems pertain to both signal and control lines in connection with pneumatic equipment. Further, the instrument box may have to be protected from dust, oil, and chemicals in the atmosphere. Where it is not practical to seal the instrument enclosure sufficiently tightly to exclude foreign materials, purging may be an attractive alternative approach. Here, the air inside the instrument case is maintained at a pressure slightly above that of the outside environment. The technique also can be used to protect electrical equipment from hazards caused by combustible gases or vapors entering the enclosure where heat or a spark might cause an explosion. See also **Intrinsic Safety**.

Changes in environmental humidity affect electrical leakage, dimensions of hygroscopic materials such as paper-recorded charts, and the concentration of chemical solutions, and, of course, the presence of dampness enhances the formation of rust and corrosion. Methods for overcoming humidity effects include sealing to exclude moisture, heating the equipment (maintaining a constant temperature) to lower the relative humidity, cooling by refrigeration to cause condensation on non-critical areas and permitting condensate removal, and the use of desiccants to absorb moisture. Pipes and tubing containing fluids that would freeze or become too viscous when subjected to very low ambient temperatures can be "steam traced" by paralleling the tubing with a small steam line.

Sometimes a practical solution for assuring satisfactory operation despite extremes of temperature is that of de-rating a component, so that its output will be adequate under the most unfavorable conditions. This applies particularly to electronic components, such as transistors, whose power dissipation decreases as the temperature rises.

The best protection against shock and vibration is careful design of the original equipment. Serious effects on the performance of transformers, capacitors, and resistors may occur unless relative motion of the materials used in constructing them is prevented, as well as motion of the entire component relative to the remainder of the circuit. Heavy parts, such as transformers, must be rigidly attached to a sufficiently rugged chassis to prevent them from breaking loose.

Grounding may be important both for low level signals (to minimize electrical noise problems) and for high power circuits (to prevent hazards to personnel). Particular note should be taken of the distinction between line power neutral and true ground. Even a small resistance between them can produce an unacceptably high voltage difference, if there is a significant current. In many low-level instrument systems, it is vital to proper operation that a common ground or shield be used for all components of the system. This can be even more important than assuring that the ground is at true earth potential. See also **Common-Mode Voltage**; and **Differential-Mode Voltage**.

Frequently, an expendable means may be used for protection, as exemplified by a fuse in an electrical circuit. Refinements include fast- and slow-blow fuses, and circuit breakers with various speeds of operation. Voltage limiting means are the neon lamp and the zener diode, which will pass essentially no current unless the voltage (to ground, or some other safe part of the circuit) exceeds the allowable value.

Hydraulic and pneumatic equivalents are rupture disks, which break to prevent pressure from exceeding a predetermined limit, and "hydraulic fuses," which are preloaded valves that close if the flow rate becomes too great.

Thermal devices with similar purposes are fusible links, as found in automatic sprinkler systems, and freeze-out plugs, which release if water freezes and expands, endangering a system.

AMBIENT PRESSURE. See **Meteorology**.

AMBIGUITY FUNCTION. In radar, a two-dimensional function of radar range and Doppler frequency, determined by the transmitted waveform, that defines the effective filter response of the radar receiver. The ambiguity function is used to examine the suitability of different transmitted waveforms for achieving accuracy, resolution, freedom from ambiguities, and reduction of unwanted clutter. In particular, it defines 1) the sidelobe response to a complex radar waveform at different Doppler frequencies, and 2) the response of a receiver to targets at other ranges and Doppler frequencies from the desired target. The ambiguity function applies to both point targets and distributed targets.

AMS

AMBLYGONITE. A rather rare compound of fluorine, lithium, aluminum, and phosphorus, (Li, Na)$AlPO_4$(F, OH). It crystallizes in the tri-clinic system; hardness, 5–5.6; sp gr 3.08; luster, vitreous to greasy or pearly; color, white to greenish, bluish, a yellowish or grayish; streak white; translucent to subtransparent.

Amblygonite occurs in pegmatite dikes and veins associated with other lithium minerals. It is used as a source of lithium salts. The name is derived from two Greek words meaning blunt and angle, in reference to its cleavage angle of 75°30′.

Amblygonite is found in Saxony; France; Australia; Brazil; Varutrask, Sweden; Karibibe, S.W. Africa; and the United States.

AMBLYOPIA. Amblyopia, or lazy eye, is poor vision in an eye that failed to develop normal sight during early childhood. It is usually caused by a lack of use of that eye because the brain has learned to favor the other eye. To protect a child's vision, amblyopia should be corrected during infancy or early childhood.

Any condition that affects normal use of the eyes and visual development can cause amblyopia. The condition is sometimes hereditary. There are three major causes of amblyopia.

1. Strabismus is the most common cause of amblyopia and often occurs in eyes that are not aligned properly or are crossed. The crossed eye turns off to avoid double vision, and the other eye takes over most of the visual function. Because the brain favors one eye over the other, the nonpreferred eye is not adequately stimulated, and the brain cells responsible for vision in that eye do not mature normally.

2. Anisometropia refers to a condition where the eyes have unequal refractive power. For instance, one eye may be nearsighted and the other farsighted. Amblyopia occurs when the brain cannot balance this difference and chooses the easier eye to use. The eyes appear normal but, because the brain is using only one eye most of the time, the other has poor vision. This type of amblyopia is hard to detect and requires careful measurement of vision.

3. A third cause of amblyopia is any eye disease or injury that prevents a clear image from being focused inside the eye. For example, cataracts, which occur when the eye's natural lens becomes cloudy, can cause amblyopia.

Unless an eye is misaligned, amblyopia is not easily detected, especially in a child. Children are often not aware that they have one strong eye and one weak eye because their sight has been that way since birth. Without obvious abnormalities, there is no way for parents to tell that a problem exists with the child's vision.

Treating the cause alone cannot cure amblyopia. Treatment always requires forcing the brain to use the nonpreferred eye. By patching the normal eye for most or part of the day, often for weeks or months, the brain must use the weaker eye. Even after vision has been restored in the amblyopic eye, part-time patching may be necessary to maintain improvement. To correct errors in focusing or to balance an unequal refractive power between both eyes, glasses may be prescribed. On occasion, special eye drops or lenses are used to blur vision in the good eye, forcing use of the amblyopic eye.

If a cataract causes amblyopia, the cloudy lens must be removed before the other eye can be patched. Following surgery, the patient may wear prescription eyeglasses or contact lenses to restore focusing, while patching improves vision.

Successful treatment of amblyopia depends on how severe the problem is and the age of the child when treatment begins. Treatment is sometimes less successful if the amblyopia is discovered after early childhood. If detected and treated early, however, vision can be improved for most children. Part-time treatment may have to continue until about age 9, after which time amblyopia usually does not return.

Correcting amblyopia can fail when the doctor's orders are not followed. Most children do not like eye patches, especially if they have been depending on the patched eye to see clearly. See also **Cataract**; **Strabismus (Cross-Eyes)**; and **Vision and the Eye**.

Vision Rx, Inc., Elmsford, NY

AMBUSH BUG *(Insecta, Hemiptera)*. Predacious bugs named for their habit of lying in wait for their prey in flowers, where their colors conceal them. They belong to the family *Phymatidae*. The forelegs of these predatory bugs are prehensile; the tibia can be folded back against the femur, and the tarsus is regressed. Most species are tropical, only two having penetrated as far as Europe and only one of these (*Phymata crassipes*) as far north as Germany. In the United States, the ambush bug (*Phymata fasciata*), a yellowish ambush bug which may be up to 12 millimeters (0.5 inch) long, is the most commonly encountered species, though other species are also found (for example, *Phymata erosa*).

AMEBIASIS (Amebic Dysentery). Amebiasis, a widespread disease of humans, causes an estimated 500 million cases (without the inclusion of China) annually. It is believed to be the third leading cause of death due to parasites. The disease is caused by pathogenic strains of the protozoan *Entamoeba histolytica*, which exists both in a stable infective cyst form and in a more fragile, potentially invasive, trophozoite form. Amebiasis is transmitted by drinking water contaminated with fecal matter from infected individuals or by eating food contaminated by infected humans or flies. Symptoms of the disease are generally centered around the gastrointestinal tract. They include amebic dysentery and sometimes appendicitis or fulminant colitis. The disease of the intestine may range from acute dysentery with chills, fever, and blood or mucoid diarrhea (amoebic dysentery), to mild abdominal discomfort with diarrhea, containing blood or mucus. Its infection is often asymptomatic. Blood-borne propagation can cause liver abscesses, and less commonly, infection of the brain or lungs. Skin ulceration may occur by extension of intestinal lesions. Recently, it was shown that *E. histolytica* has both pathogenic and nonpathogenic strains, with characteristic isoenzyme electrophoresis patterns, that occur in symptomatic and asymptomatic persons, respectively.

Acute intestinal amebic dysentery is most commonly treated with metronidazole (**1**, Flagyl) (Table 1). An alternative drug is iodoquinol (**2**, diiodohydroxyquin, diiodohydroxyquinoline [CAS: 83-73-8]), which has also been used advantageously in combination with metronidazole or oxytetracycline (**3**, Terramycin [CAS: 79-57-2]). For patients too sick to take iodoquinol orally, emetine **(4)** or dehydroemetine (**5**, 2,3-dehydroemetine) hydrochloride is administered either subcutaneously or intramuscularly. The latter sometimes is followed by chloroquine (**6**, Aralen) phosphate or iodoquinol. Because emetine and dehydroemetine cause cardiac arrhythmias, muscle weakness, and inflammation at the injection site, these toxic compounds are used primarily for patients whose lives are threatened by the disease. Antibiotics, such as tetracycline (**7**, Achromycin [CAS: 60-54-8]) and paromomycin (**8**, Humatin), are also effective against moderate intestinal amebiasis.

Extraintestinal (eg, hepatic) amebiasis is treated with metronidazole and can be followed by iodoquinol or a combination of dehydroemetine or emetine hydrochloride with chloroquine phosphate. Iodoquinol is the drug of choice for asymptomatic amebiasis, whereas diloxanide furoate (**9**, Furamide) has been used successfully to treat symptomatic and asymptomatic intestinal amebic cyst carriers.

Other compounds that have shown promising properties *in vitro* against *E. histolytica* are niridazole **(10)**, tinidazole (**11**, Fasigyn, Simplotan), gossypol **(12)**, bithionol [**(13)**, 2,2′-thiobis(4,6-dichlorophenol)], and pimaricin (**14**, Natamycin [CAS: 7681-93-8]). The chemotherapy of amebiasis has been reviewed [Knight, 1980].

Related amoeba that cause infections of lower incidence but greater severity are the invasive organisms *Naegleria fowleri* and species of *Acanthamoeba* such as *A. castellanii* and *A. polyphaga*. These amoeba are free-living in the soil or warm fresh water, occur widely, and affect many animals but have no known animal reservoir. Entry of *Naegleria* into the body usually is by the nasal passages, whereas *Acanthamoeba* can enter via the eye, skin, or lung. They cause primary amebic meningoencephalitis (PAM), an infection of the central nervous system that is usually fatal. Symptoms in humans include severe headache, confusion, nausea, seizures, and coma. Frequently the olfactory tract is affected. These infections are considered opportunistic and are seen to a greater extent in immunosuppressed humans (due to AIDS, steroids, radiotherapy, or chemotherapy) than in those who are healthy.

TABLE 1. AMEBIASIS ANTIPROTOZOAL AGENTS[a]

Structure number	Compound name	CAS Registry Number	Molecular formula	Structure
(1)	metranodazole[b,c,d,e,f]	[443-48-1]	$C_6H_9N_3O_3$	(2)	iodoquinol[b,d]	[83-73-8]	$C_9H_5I_2NO$	(3)	oxytetracycline[b,g,h]	[79-57-2]	$C_{22}H_{24}N_2O_9$	(4)	emetine (HCl)	[316-42-7]	$C_{29}H_{40}N_2O_4 \cdot 2ClH$	(5)	dehydroemetine	[4914-30-1]	$C_{29}H_{38}N_2O_4$	(6)	chloroquine[g,i,j] (diphosphate)	[50-63-5]	$C_8H_{26}ClN_3 \cdot 2H_3O_4P$	(7)	tetracycline[b,j]	[60-54-8]	$C_{22}H_{24}N_2O_8$

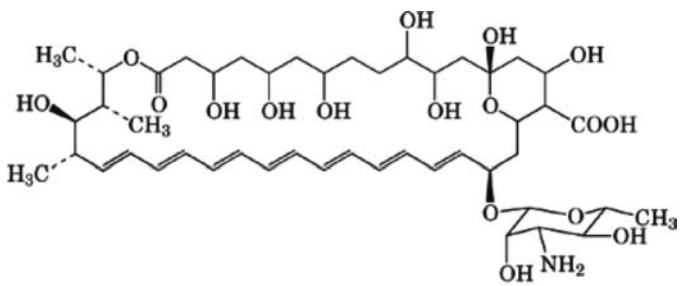
[a] Other applications of these agents are indicated in footnotes to the table.
[b] Balantidiasis.
[c] Giardiasis.
[d] Hexamitosis.
[e] Histomoniasis.
[f] Trichomoniasi
[g] Anaplasmosis.
[h] Theileriasis.
[i] Babesiasis.
[j] Malaria.
[k] Leishmaniasis.

Naegleria is treatable with intravenous amphotericin B (**15**, Fungizone), a toxic drug that must be used with caution.



(15)

A combination of amphotericin B, miconazole **(16)**, and rifampin **(17)** was used to successfully cure one patient. In addition, tetracycline **(7)** and minocycline **(18)** have been recommended although their clinical efficacy has not been established. No proven therapeutic agents exist for treating *Acathamoeba* infections; however, the phenothiazines, trifluoperazine [CAS: 117-89-5] and chlorpromazine [CAS: 50-53-3], show promise *in vitro*.

AMEIVA *(Reptilia, Sauria).* A lizard of Central and South America: small, very active, timid, and mainly insectivorous. The name is that of the genus, applied as a common name to the score of included species.

AMENORRHEA. The absence of menstruation, which may be primary or secondary. Secondary amenorrhea is defined as the absence of menstruation in a woman who has had previously normal menstrual periods. The most obvious cause of this, of course, is pregnancy. The physician will probe into four possible areas of dysfunction in attempting to comprehend a particular primary or secondary amenorrhea — hypothalamic, pituitary, ovarian, and uterine defects. See **Gonads**; and **Hormones**.

AMERICAN TRYPANOSOMIASIS. See **Chaga's Disease (South American Trypanosomiasis)**.

AMERICIUM. [CAS: 7440-35-9] Chemical element, symbol Am, at no. 95, at. wt. 243 (mass number of the most stable isotope), radioactive metal of the actinide series, also one of the transuranium elements. All isotopes of americium are radioactive; all must be produced synthetically. The element was discovered by G.T. Seaborg and associates at the Metallurgical Laboratory of the University of Chicago in 1945. At that time, the element was obtained by bombarding uranium-238 with helium ions to produce ^{241}Am, which has a half-life of 475 years. Subsequently, ^{241}Am has been produced by bombardment of plutonium-241 with neutrons in a nuclear reactor. ^{243}Am is the most stable isotope, an alpha emitter with a half-life of 7950 years. Other known isotopes are ^{237}Am, ^{238}Am, ^{240}Am, ^{241}Am, ^{242}Am, ^{244}Am, ^{245}Am, and ^{246}Am. Electronic configuration is $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 5d^{10} 5f^7 6s^2 6p^6 7s^2$. Ionic radii are: Am^{4+}, 0.85 Å; Am^{3+}, 1.00 Å.

This element exists in acidic aqueous solution in the (III), (IV), (V), and (VI) oxidation states with the ionic species probably corresponding to Am^{3+}, Am^{4+}, AmO_2^{+} and AmO_2^{2+}.

The colors of the ions are: Am^{3+}, pink; Am^{4+}, rose; AmO_2^{+}, yellow; and AmO_2^{2+}, rum-colored.

It can be seen that the (III) state is highly stable with respect to disproportionation in aqueous solution and is extremely difficult to oxidize or reduce. There is evidence for the existence of the (II) state since tracer amounts of americium have been reduced by sodium amalgam and precipitated with barium chloride or europium sulfate as carrier. The (IV) state is very unstable in solution: the potential for americium(III)-americium(IV) was determined by thermal measurements involving solid AmO_2. Americium can be oxidized to the (V) or (VI) state with strong oxidizing agents, and the potential for the americium(V)-americium(VI) couple was determined potentiometrically.

In its precipitation reactions americium(III) is very similar to the other tripositive actinide elements and to the rare earth elements. Thus the fluoride and the oxalate are insoluble and the phosphate and iodate are only moderately soluble in acid solution, whereas the nitrates, halides, sulfates, sulfides, and perchlorates are all soluble. Americium(VI) can be precipitated with sodium acetate giving crystals isostructural with sodium uranyl acetate,

$$NaUO_2(C_2H_3O_2)_3{\cdot}xH_2O$$

and the corresponding neptunium and plutonium compounds.

Of the hydrides of americium, both AmH_2 and Am_4H_{15} are black and cubic.

When americium is precipitated as the insoluble hydroxide from aqueous solution and heated in air, a black oxide is formed which corresponds almost exactly to the formula AmO_2. This may be reduced to Am_2O_3 through the action of hydrogen at elevated temperatures. The AmO_2 has the cubic fluorite type structure, isostructural with UO_2, NpO_2, and PuO_2. The sesquioxide, Am_2O_3 is allotropic, existing in a reddish brown and a tan form, both hexagonal. As in the case of the preceding actinide elements, oxides of variable composition between $AmO_{1.5}$ and AmO_2 are formed depending upon the conditions.

All four of the trihalides of americium have been prepared and identified. These are prepared by methods similar to those used in the preparation of the trihalides of other actinide elements. AmF_3 is pink and hexagonal, as is $AmCl_3$; $AmBr_3$ is white and orthorhombic; while a tetrafluoride, AmF_4 is tan and monoclinic.

In research at the Institute of Radiochemistry, Karlsruhe, West Germany during the early 1970s, investigators prepared alloys of americium with platinum, palladium, and iridium. These alloys were prepared by hydrogen reduction of the americium oxide in the presence of finely divided noble metals according to:

$$Am_2O_3 + 10Pt \xrightarrow[1100\,^{\circ}C]{H_2} 2\ AmPt_5 + H_2O$$

The reaction is called a *coupled reaction* because the reduction of the metal oxide can be done only in the presence of noble metals. The hydrogen must be extremely pure, with an oxygen content of less than 10^{-25} torr.

See also **Chemical Elements**.

Industrial utilization of americium has been quite limited. Uses include a portable source for gamma radiography, a radioactive glass thickness gage for the flat glass industry, and an ionization source for smoke detectors.

Americium is present in significant quantities in spent nuclear reactor fuel and poses a threat to the environment. A group of scientists at the U.S. Geological Survey (Denver, Colorado) has studied the chemical speciation of actinium (and neptunium) in ground waters associated with rock types that have been proposed as possible hosts for nuclear waste repositories. Researchers Cleveland, Nash, and Rees (see reference list) concluded that americium (and neptunium) are relatively insoluble in ground waters containing high sulfate concentrations (90 °C).

AMETHYST. A purple- or violet-colored quartz having the same physical characteristics as quartz. The source of color is not definite but thought to be caused by ferric iron contamination. Oriental amethysts are purple corundum.

Amethysts are found in the Ural Mountains, India, Sri Lanka, Madagascar, Uruguay, Brazil, the Thunder Bay district of Lake Superior in Ontario, and Nova Scotia; in the United States, in Michigan, Virginia, North Carolina, Montana, and Maine.

The name amethyst is generally supposed to have been derived from the Greek word meaning not drunken. Pliny suggested that the term was applied because the amethyst approaches but is not quite the equivalent of a wine color.

See also **Quartz**.

AMICRON. A name applied by Zsigmondy to individual dispersed particles invisible under the ultramicroscope whose size is about 10^{-7} cm. They act as nuclei for the formation of submicrons which are about five times as large.

AMIDES. An amide may be defined as a compound that contains the $CO{\cdot}NH_2$ radical, or an acid radical(s) substituted for one or more of the hydrogen atoms of an ammonia molecule. Amides may be classified as (1) *primary amides*, which contain one acyl radical, such as $-CO{\cdot}CH_3$ (acetyl) or $-CO{\cdot}C_6H_5$ (benzoyl), linked to the *amido* group ($-NH_2$). Thus, acetamide NH_2COCH_3 is a combination of the acetyl and amido groups; (2) *secondary amides*, which contain two acyl radicals and the *imido* group ($=NH_2$) Diacetamide $HN(COCH_3)_2$ is an example; and (3) *tertiary amides*, which contain three acyl radicals attached to the N atom. Triacetamide $N(COCH_3)_3$ is an example.

A further structural analysis will show that amides may be regarded as derivatives of corresponding acids in which the amido group substitutes

for the hydroxyl radical OH of the carboxylic group COOH. Thus, in the instance of formic acid HCOOH, the amide is $HCOONH_2$ (formamide); or in the case of acetic acid CH_3COOH, the amide is CH_3CONH_2 (acetamide). Similarly, urea may be regarded as the amide of carbonic acid (theoretical) O:C, that is, NH_2CONH_2 (urea). The latter represents a dibasic acid in which two H atoms of the hydroxyl groups have been replaced by amido groups. A similar instance, malamide,

$$NH_2CO{\cdot}CH_2CH(OH){\cdot}CONH_2$$

is derived from the dibasic acid, malic acid,

$$OHCO{\cdot}CH_2CH(OH){\cdot}COOH.$$

Aromatic amides, sometimes referred to as *arylamides*, exhibit the same relationship. Note the relationship of benzoic acid C_6H_5COOH with benzamide $C_6H_5CONH_2$. *Thiamides* are derived from amides in which there is substitution of the O atom by a sulfur atom. Thus, acetamide $NH_2{\cdot}CO{\cdot}CH_3$, becomes thiacetamide $NH_2{\cdot}CS{\cdot}CH_3$; or acetanilide $C_6H_5{\cdot}NH{\cdot}CO{\cdot}CH_3$ becomes thiacetanilide $C_6H_5{\cdot}NH{\cdot}CS{\cdot}CH_3$. *Sulfonamides* are derived from the sulfonic acids. Thus, benzene-sulfonic acid $C_6H_5{\cdot}SO_2{\cdot}OH$ becomes benzene-sulfonamide $C_6H_5{\cdot}SO_2{\cdot}NH_2$. See also **Sulfonamide Drugs**.

Amides may be made in a number of ways. Prominent among them is the acylation of amines. The agents commonly used are, in order of reactivity, the acid halides, acid anhydrides, and esters. Such reactions are:

$$R'COCl + HNR_2 \longrightarrow R'C(=O)NR_2 + HCl$$

$$R'C(=O)OC(=O)R' + HNR_2 \longrightarrow R'C(=O)NR_2 + R'COOH$$

$$R'C(=O)OR'' + HNR_2 \longrightarrow R'C(=O)NR_2 + R''OH$$

The hydrolysis of nitriles also yields amides:

$$RCN + H_2O \xrightarrow{OH} RCONH_2$$

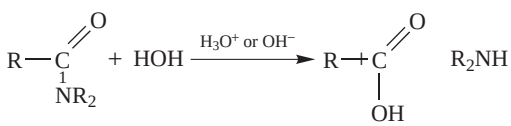
Amides are resonance compounds, having an ionic structure for one form:

$$R{-}C(=O)NR_2 \qquad R{-}C(-O^-) : N^+R_2$$

Evidence for the ionic form is provided by the fact that the carbon-nitrogen bond (1.38 Å) is shorter than a normal C−N bond (1.47 Å) and the carbon-oxygen bond (1.28 Å) is longer than a typical carbonyl bond (1.21 Å). That is, the carbon-nitrogen bond is neither a real C−N single bond nor a C=N double bond.

The amides are sharp-melting crystalline compounds and make good derivatives for any of the acyl classes of compounds, i.e., esters, acids, acid halides, anhydrides, and lactones.

Amides undergo hydrolysis upon refluxing in H_2O. The reaction is catalyzed by acid or alkali.



Primary amides may be dehydrated to yield nitriles.

$$R{-}CONH_2 + C_6H_5SO_2Cl \xrightarrow[70^\circ]{\text{pyridine}} R{-}CN + C_6H_5SO_3H + HCl$$

The reaction is run in pyridine solutions.

Primary and secondary amides of the type $RCONH_2$ and RCONHR react with nitrous acid in the same way as do the corresponding primary and secondary amines.

$$RCONH_2 + HONO \longrightarrow RCOOH + N_2 + HOH$$

$$RCONHR + HONO \longrightarrow RCON(NO)R + HOH$$

When diamides having their amide groups not far apart are heated, they lose ammonia to yield imides. See also **Imides**.

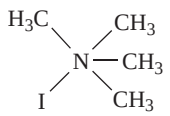
AMINATION. The process of introducing the amino group ($-NH_2$) into an organic compound is termed *amination*. An example is the reduction of aniline, $C_6H_5{\cdot}NH_2$, from nitrobenzene, $C_6H_5{\cdot}NO_2$. The reduction may be accomplished with iron and HCl. Only about 2% of the calculated amount of acid (to produce H_2 by reaction with iron) is required because of the fact that H_2O plus iron in the presence of ferrous chloride solution (ferrous and chloride ions) functions as the primary reducing agent. Such groups as nitroso (−NO), hydroxylamine (−NH·NH−), and azo (−N:N−) also yield amines by reduction. Amination also may be effected by the use of NH_3, in a process sometimes referred to as *ammonolysis*. An example is the production of aniline from chlorobenzene:

$$C_6H_5Cl + NH_3 \longrightarrow C_6H_5{\cdot}NH_2 + HCl$$

The reaction proceeds only under high pressure. In the ammonolysis of benzenoid sulfonic acid derivatives, an oxidizing agent is added to prevent the formation of soluble reduction products, such as $NaNH_4SO_4$, which commonly form. Oxygen-function compounds also may be subjected to ammonolysis: (1) methanol plus aluminum phosphate catalyst yields mono-, di-, and trimethylamines; (2) β-naphthol plus sodium ammonium sulfite catalyst (Bucherer reaction) yields β-naphthylamine; (3) ethylene oxide yields mono-, di-, and triethanolamines; (4) glucose plus nickel catalyst yields glucamine; and (5) cyclohexanone plus nickel catalyst yields cyclohexylamine.

AMINES. An amine is a derivative of NH_3 in which there is a replacement for one or more of the H atoms of NH_3 by an alkyl group, such as $-CH_3$ (methyl) or $-C_2H_5$ (ethyl); or by an aryl group, such as $-C_6H_5$ (phenyl) or $-C_{10}H_7$ (naphthyl). Mixed amines contain at least one alkyl and one aryl group as exemplified by methylphenylamine $CH_3{\cdot}N(H){\cdot}C_6H_5$. When one, two, and three H atoms are thus replaced, the resulting amines are known as *primary*, *secondary*, and *tertiary*, respectively. Thus, methylamine, CH_3NH_2, is a primary amine; dimethylamine, $(CH_3)_2NH$, is a secondary amine; and trimethylamine, $(CH_3)_3N$, is a tertiary amine. Secondary amines sometimes are called *imines*; tertiary amines, *nitriles*.

Quaternary amines consist of four alkyl or aryl groups attached to an N atom and, therefore, may be considered substituted ammonium bases. Commonly, they are referred to in the trade as quaternary ammonium compounds. An example is tetramethyl ammonium iodide.



The amines and quaternary ammonium compounds, exhibiting such great versatility for forming substitution products, are very important starting and intermediate materials for industrial organic syntheses, both on a small scale for preparing rare compounds for use in research and on a tonnage basis for the preparation of resins, plastics, and other synthetics. Very important industrially are the ethanolamines which are excellent absorbents for certain materials. See also **Ethanolamines**. Hexamethylene tetramine is a high-tonnage product used in plastics production. See also **Hexamine**. Phenylamine (aniline), although not as important industrially as it was some years ago, still is produced in quantity. Melamine is produced on a large scale and is the base for a series of important resins. See also **Melamine**. There are numerous amines and quaternary ammonium compounds that are not well known because of their importance as intermediates rather than as final products. Examples along these lines may include acetonitrile and acrylonitrile. See also **Acrylonitrile**.

Primary amines react (1) with nitrous acid, yielding (a) with alkylamine, nitrogen gas plus alcohol, (b) with warm arylamine, nitrogen gas plus phenol (the amino-group of primary amines is displaced by the hydroxyl group to form alcohol or phenol), (c) with cold arylamine, diazonium compounds, (2) with acetyl chloride or benzoyl chloride, yielding substituted amides, thus, ethylamine plus acetyl chloride forms *N*-ethylacetamide, $C_2H_5NHOCCH_3$, (3) with benzene-sulfonyl chloride, $C_6H_5SO_2Cl$, yielding substituted benzene sulfonamides, thus, ethylamine forms *N*-ethylbenzenesulfonamide, $C_6H_5SO_2{-}NHC_2H_5$, soluble in sodium hydroxide, (4) with chloroform, $CHCl_3$ with a base, yielding isocyanides (5) with HNO_3 (concentrated), yielding nitra-mines, thus, ethylamine reacts to form ethylnitramine, $C_2H_5{-}NHNO_2$.

Secondary amines react (1) with nitrous acid, yielding nitrosamines, yellow oily liquids, volatile in steam, soluble in ether. The secondary amine may be recovered by heating the nitrosamine with concentrated HCl, or

hydrazines may be formed by reduction of the nitrosamines, e.g., methylaniline from methylphenylnitrosamine, $CH_3(C_6H_5)NNO$, reduction yielding unsymmetrical methylphenylhydrazine, $CH_3(C_6H_5)NHNH_2$, (2) with acetyl or benzoyl chloride, yielding substituted amides, thus, diethylamine plus acetyl chloride to form *N*,*N*-diethylacetamide $(C_2H_5)-NOCCH_3$, (3) with benzene sulfonyl chloride, yielding substituted benzene sulfonamides, thus, diethylamine reacts to form *N*,*N*-diethylbenzenesulfonamide, $C_6H_5SO_2N(C_2H_5)_2$, insoluble in NaOH.

Tertiary amines do not react with nitrous acid, acetyl chloride, benzoyl chloride, benzenesulfonyl chloride, but react with alkyl halides to form quaternary ammonium halides, which are converted by silver hydroxide to quaternary ammonium hydroxides. Quaternary ammonium hydroxides upon heating yield (1) tertiary amine plus alcohol (or, for higher members, olefin plus water). Tertiary amines may also be formed (2) by alkylation of secondary amines, e.g., by dimethyl sulfate, (3) from amino acids by living organisms, e.g., decomposition of fish in the case of trimethylamine.

AMINO ACIDS. The scores of proteins which make up about one-half of the dry weight of the human body and that are so vital to life functions are made up of a number of amino acids in various combinations and configurations. The manner in which the complex protein structures are assembled from amino acids is described in the entry on Protein. For some users of this book, it may be helpful to scan that portion of the protein entry that deals with the chemical nature of proteins prior to considering the details of this immediate entry on amino acids.

Although the proteins resulting from amino acid assembly are ultimately among the most important chemicals in the animal body (as well as plants), the so-called infrastructure of the proteins is dependent upon the amino acid building blocks. Although there are many hundreds of amino acids, only about 20 of these are considered very important to living processes, of which six to ten are classified as essential. Another three or four may be classified as quasi-essential, and ten to twelve may be categorized as nonessential. As more is learned about the fundamentals, protein chemistry, the scientific importance attached to specific amino acids varies. Usually, as the learning process continues, the findings tend to increase the importance of specific amino acids. Actually, the words *essential* and *nonessential* are not very good choices for naming categories of amino acids. Generally, those amino acids that the human body cannot synthesize at all or at a rate commensurate with its needs are called *essential amino acids* (EAA). In other words, for the growth and maintenance of a normal healthy body, it is essential that these amino acids be ingested as part of the diet and in the necessary quantities. To illustrate some of the indefinite character of amino acid nomenclature, some authorities classify histidine as an essential amino acid; others do not. The fact is that histidine is essential for the normal growth of the human infant, but to date it is not regarded as essential for adults. By extension of the preceding explanation, the term nonessential is taken to mean those amino acids that are really synthesized in the body and hence need not be present in food intake. This classification of amino acids, although amenable to change as the results of new findings, has been quite convenient in planning the dietary needs of people as well as of farm animals, pets, and also in terms of those plants that are of economic importance. The classification has been particularly helpful in planning the specific nutritional content of food substances involved in various aid and related programs for the people in needy and underdeveloped areas of the world.

Food Fortification with Amino Acids. In a report of the World Health Organization, the following observation has been made: "To determine the quality of a protein, two factors have to be distinguished, namely, the proportion of essential to nonessential amino acids and, secondly, the relative amounts of the essential amino acids... The best pattern of essential amino acids for meeting human requirements was that found in whole egg protein or human milk, and comparisons of protein quality should be made by reference to the essential amino acid patterns of either of these two proteins." The ratio of each essential amino acid to the total sum is given for hen's egg and human and cow's milk in Table 1.

In the human body, tyrosine and cysteine can be formed from phenylalanine and methionine, respectively. The reverse transformations do not occur. Human infants have an ability to synthesize arginine and histidine in their bodies, but the speed of the process is slow compared with requirements.

TABLE 1. REPRESENTATIVE ESSENTIAL AMINO ACID PATTERNS *A/E RATIO (MILLIGRAMS PER GRAM OF TOTAL ESSENTIAL AMINO ACIDS)

	Hen's Egg (Whole)	Human Milk	Cow's Milk
Total "aromatic" amino acids	195	226	197
Phenylalanine	(114)	(114)	(97)
Tyrosine	(81)	(112)	(100)
Leucine	172	184	196
Valine	141	147	137
Isoleucine	129	132	127
Lysine	125	128	155
Total "S"	107	87	65
Cystine	(46)	(43)	(17)
Methionine	(61)	(44)	(48)
Threonine	99	99	91
Tryptophan	31	34	28

Source: World Health Organization; FAO Nutrition Meeting Report Series, No. 37, Geneva, 1965.

*A/E Ratio equals ten times percentage of single essential amino acid to the total essential amino acids contained.

Several essential amino acids have been shown to be the limiting factor of nutrition in plant proteins. In advanced countries, the ratio of vegetable proteins to animal proteins in foods is 1.4:1. In underdeveloped nations, the ratio is 3.5:1, which means that people in underdeveloped areas depend upon vegetable proteins. Among vegetable staple foods, wheat easily can be fortified. It is used as flour all over the world. L-Lysine hydrochloride (0.2%) is added to the flour. Wheat bread fortified with lysine is used in several areas of the world; in Japan it is supplied as a school ration.

The situation of fortification in rice is somewhat more complex. Before cooking, rice must be washed (polished) with water. In some countries, the cooking water is allowed to boil over or is discarded. This significant loss of fortified amino acids must be considered. L-Lysine hydrochloride (0.2%) and L-threonine (0.1%) are shaped like rice grain with other nutrients and enveloped in a film. The added materials must hold the initial shape and not dissolve out during boiling, but be easily freed of their coating in the digestive organs.

The amino acids are arranged in accordance with essentiality in Table 2. Each of the four amino acids at the start of the table are all limiting factors of various vegetable proteins. Chick feed usually is supplemented with fish meal, but where the latter is in limited supply, soybean meals are substituted. The demand for DL-methionine, limiting amino acid in soybean meals, is now increasing. When seed meals, such as corn and sorghum, are used as feeds for chickens or pigs, L-lysine hydrochloride must be added for fortification. Lysine production is increasing upward to the level of methionine.

Early Research and Isolation of Amino Acids. Because of such rapid studies made within the past few decades in biochemistry and nutrition, these sciences still have a challenging aura about them. But, it is interesting to note that the first two natural amino acids were isolated by Braconnot in 1820. As shown by Table 3, these two compounds were glycine and leucine. Bopp isolated tyrosine from casein in 1849. Additional amino acids were isolated during the 1880s, but the real thrust into research in this field commenced in the very late 1800s and early 1900s with the work of Emden, Fischer, Mörner, and Hopkins and Cole. It is interesting to observe that Emil Fischer (1852–1919), German chemist and pioneer in the fields of purines and polypeptides, isolated three of these important compounds, namely, proline from gelatin in 1901, valine from casein in 1901, and hydroxyproline from gelatin in 1902. As an understanding of the role of amino acids in protein formation and of the function of proteins in nutrition progressed, the pathway was prepared for further isolation of amino acids. For example, in 1907, a combined committee representing the American Society of Biological Chemists and the American Physiological Society, proposed a formal classification of proteins into three major categories: (1) simple proteins, (2) conjugated proteins, and (3) derived proteins. The last classification embraces all denatured proteins and hydrolytic products or protein breakdown and no longer is considered as a general class.

Very approximate annual worldwide production of amino acids, their current method of preparation (not exclusive), and general characteristics are given in Table 2.

TABLE 2. IMPORTANT NATURAL AMINO ACIDS AND PRODUCTION

Amino Acid	World Annual Production, tons	Present Mode of Manufacture	Characteristics
Essential Amino Acids			
DL-Methionine	10^4	Synthesis from acrolein and mercaptan	First limiting amino acid for soybean
L-Lysine. HCl	10^3	Fermentation (AM)*	First limiting amino acid for cereals
L-Threonine	10	Fermentation (AM)	Second limiting amino acid for rice
L-Tryptophan	10	Synthesis from acrylonitrile and resolution	Second limiting amino acid for corn
L-Phenylalanine	10	Synthesis from phenyl-acetaldehyde and resolution	Rich in plant protein
L-Valine	10	Fermentation (AM)	
L-Leucine	10	Extraction from protein	
L-Isoleucine	10	Fermentation (WS)**	Deficient in some cases
Quasi-Essential Amino Acids			
L-Arginine. HCl	10^2	Synthesis from *L*-ornithine Fermentation (AM)	Essential to human infants
L-Histidine. HCl	10	Extraction from protein	
L-Tyrosine	10	Enzymation of phenol and Serine	Limited substitute for phenylalanine
L-Cysteine L-Cystine	10	Extraction from human hair	Limited substitute for methionine
Nonessential Amino Acids			
L-Glutamic acid	10^5	Fermentation (WS) Synthesis from acrylonitrile and resolution	MSG, taste enhancer
Glycine	10^3	Synthesis from formaldehyde	Sweetener
DL-Alanine	10^2	Synthesis from acetaldehyde	
L-Aspartic acid	10^2	Enzymation of fumaric acid	Hygienic drug
L-Glutamine	10^2	Fermentation (WS)	Anti-gastroduodenal ulcer drug
L-Serine	<10	Syntheisis from glycolonitrile and resolution	Rich in raw silk
L-Proline	<10	Fermentation (AM)	Rich in gelatin
L-Hydroxyproline	<10	Extraction from gelatin	
L-Asparagine	<10	Synthesis from L-aspartic acid	Neurotropic metabolic regulator
L-Alanine	<10	Enzymation of L-aspartic acid	Rich in degummed white silk
L-Dihydroxy-phenylalanine	10^2	Synthesis from piperonal, vanillin, or acrylonitrile and resolution	Specific drug for Parkinson's disease
L-Citrulline	<10	Fermentation (AM)	Ammonia detoxicant
L-Ornithine	<10	Fermentation (AM)	

*AM, artificial mutant; **WS, wild strain. MSG, monosodium glutamate.

TABLE 3. FIRST ISOLATION OF AMINO ACIDS

Abbreviation	Name and Formula	First Isolation and (Source)	Isoelectric Point
	Neutral Amino Acids-Aliphatic Type		
Ala	Alanine 	1879 by Schutzenberger 1888 by Weyl (silk fibroin)	6.0
Gly	Glycine 	1820 by Braconnot (gelatin)	6.0
Ile	Isoleucine 	1904 by Ehrlich (fibrin)	6.0
Leu	Leucine 	1820 by Braconnot (muscle fiber; wool)	6.0
Val	Valine 	1901 by Fischer (casein)	6.0
	Neutral Amino Acids — Hydroxy Type		
Ser	Serine 	1865 by Cramer (sericine)	5.7

The *isoelectric point* is very important in the preparation and separation of amino acids and proteins. Protein solubility varies markedly with pH and is at a minimum at the isoelectric point. By raising the salt concentration and adjusting pH to the isoelectric point, it is often possible to obtain a precipitate considerably enriched in the desired protein and to crystallize it from a heterogenous mixture.

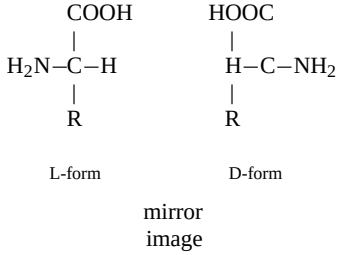
Chemical Nature of Amino Acids

In a very general way, an amino acid is any organic acid that incorporates one or more amino groups. This definition includes a multitude of substances of most diverse structure. There are seemingly limitless related compounds of differing molecular size and constitution which incorporate varying kinds and numbers of functional groups. Most extensive study has centered on the relatively small group of alpha-amino acids that are combined in amide linkage to form proteins. With few exceptions, these compounds possess the general structure NH_2CHRCO_2H, where the amino group occupies a position on the carbon atom alpha to that of the carboxyl group, and where the side chain R may be of diverse composition and structure.

Few products of natural origin are as versatile in their behavior and properties as are the amino acids, and few have such a variety of biological duties to perform. Among their general characteristics would be included:

(a) Water-soluble and amphoteric electrolytes, with the ability to form acid salts and basic salts and thus act as buffers over at least two ranges of pH (hydrogen ion concentration).
(b) Dipolar ions of high electric moment with a considerable capacity to increase the dielectric constant of the medium in which they are dissolved.
(c) Compounds with reactive groups capable of a wide range of chemical alterations leading readily to a large variety of degradation, synthetic, and transformation products, such as esters, amides, amines, anhydrides, polymers, polypeptides, diketopiperazines, hydroxy acids, halogenated acids, keto acids, acylated acids, mercaptans, shorter-or longer-chained acids, and pyrrolidine and piperidine ring forms.
(d) Indispensable components of the diet of all animals including humans.
(e) Participants in crucial metabolic reactions on which life depends, and substrates for a variety of specific enzymes in vitro.
(f) Binders of metals of many kinds.

Optical Properties. With the exception of glycine ($NH_2CH_2CO_2H$) and amino-malonic acid [$NH_2CH(CO_2H)_2$], all α-amino acids which are classifiable according to the general formula previously given exist in at least two different optically isometric forms. The optical isomers of a given amino acid possess identical empirical and structural formulas, and are indistinguishable from each other on the basis of their chemical and physical properties, with the singular exception of their effect on plane polarized light. This may be illustrated with the two optically active forms as shown by



One form (L-form) exhibits the ability to rotate the plane of polarization of plane polarized light to the left (levorotatory), whereas the other form (D-form) rotates the plane to the right (dextrorotatory). Although the direction of optical rotation exhibited by these optically active forms is different, the magnitude of their respective rotations is the same. If equal amounts of *dextro* and *levo* forms are admixed, the optical effect of each isomer is neutralized by the other, and an optically inactive product known as a *racemic modification* or *racemate* is secured.

The ability of the alanine molecule, for example, to exist in two stereoisomeric forms can be attributed to the fact that the α-carbon atom of this compound is attached to four different groups which may vary in their three-dimensional spatial arrangement. Compounds of this type do not possess complete symmetry when viewed from a purely geometrical standpoint and hence are generally referred to as *asymmetric*. As a consequence of this molecular asymmetry, the four covalent bonds of an asymmetric carbon atom can be aligned in a manner such that a regular tetrahedron is formed by the straight lines connecting their ends. Hence, two different tetrahedral arrangements of the groups about the asymmetric carbon atom can be devised so that these structures relate to one another as an object relates to its mirror image, or as the right hand relates to the left hand. Molecules of this type are endowed with the property of optical activity and, together with their nonsuperimposable mirror images, are generally referred to as *enantiomorphs*, *enantiomers*, *antimers*, or *optical antipodes*.

Classification. In accordance with the structure of the R-group, the amino acids of primary importance can be classified into eight groups. Additional amino acids composing protein are not included in this classification, because they occur infrequently. See Table 4.

TABLE 4. STRUCTURAL CLASSIFICATION OF AMINO ACIDS

NEUTRAL AMINO ACIDS

BASIC AMINO ACIDS		
Histidine		
Lysine		
Arginine		
IMINO ACIDS		
Proline		
Hydroxyproline		

Normally, amino acids exist as dipolar ions. $RCH(NH_3^+)COO^-$, in a neutral state, where both amino and carboxyl groups are ionized. The dipolar form, $RCH(NH_2)COOH$ may be considered, but the dipolar form predominates for the usual monoamino monocarboxylic acid and it is estimated that these forms occur 10^5 to 10^6 times more frequently than the non-polar forms. Amino acids decompose thermally at what might be considered a relatively high temperature (200–300 °C). The compounds are practically insoluble in organic solvents, have low vapor pressure, and do not exhibit a precisely defined melting point.

The ionic states of a simple α-amino acid are given by

$$\underset{\text{(Cationic form; acidic)}}{RCH(NH_3^+)COOH} \underset{+H^+}{\overset{-H+(K_1)}{\rightleftharpoons}}$$

$$\underset{\text{(Dipolar form; neutral)}}{RCH(NH_3^+)COO^-} \underset{+H^+}{\overset{-H+(K_2)}{\rightleftharpoons}} \underset{\text{(Anionic form; basic)}}{RCH(NH_2)COO^-}$$

In accordance with the change of the ionic state, dissociation constants are

$$K_1(COOH) = \frac{[H^+][RCH(NH_3^+)COO^-]}{[RCH(NH_3^+)COOH]}$$

$$K_2(NH_3^+) = \frac{[H^+][RCH(NH_2)COO^-]}{[RCH(NH_3^+)COO^-]}$$

In as much as $pK = -\log K$, the values for glycine are $pK_1 = 2.34$ and $pK_2 = 9.60$ (in aqueous solution at 25°C). The homologous amino acids indicate similar values. The pH at which acidic ionization balances basic ionization is termed the *isoelectric point* (pH_1), (corresponding to

$$[RCH(NH_3^+)COOH] = [RCH(NH_2)COO^-]$$

Thus, from these formulas, the pH_1 is

$$pH_1 = \tfrac{1}{2}(pK_1 + pK_2)$$

Formation of Salts. Amino acids have certain characteristics of both organic bases and organic acids because they are amphoteric. As amines, the amino acids form stable salts, such as hydrochlorides or aromatic sulfonic acid salts. These are used as selective precipitants of certain amino acids. As organic acids, the amino acids form complex salts with heavy metals, the less soluble salt being used for amino acid separation.

Esters. When heated with the equivalent amount of a strong acid, usually hydrochloric acid in absolute alcohol, amino acids form esters. These are obtained as hydrochlorides.

Acylation. In alkaline solution, amino acids react with acid chlorides or acid anhydrides to form acyl compounds of the type

$$\begin{array}{l} RCH-COONa \\ \quad | \\ NHCOR' \end{array}$$

Van Slyke Reaction (Deamination). With excess nitrous acid, -amino acids react to form -hydroxyl acids on a quantitative basis. Nitrogen gas is generated.

$$\begin{array}{l} RCH-COOH \\ \quad | \\ NH_2 \end{array} + HNO_2 \longrightarrow \begin{array}{l} RCH-COOH \\ \quad | \\ OH \end{array} + N_2 + H_2O$$

The reaction is completed within five minutes at room temperature. Thus, measurement of the volume of nitrogen generated can be used in amino acid determinations.

Decarboxylation. When heated with inert solvents, such as kerosene, amino acids form amines

$$\begin{array}{l} RCH-COOH \\ \quad | \\ NH_2 \end{array} \longrightarrow \begin{array}{l} RCH_2 \\ \quad | \\ NH_2 \end{array} + CO_2$$

Decarboxylative enzymes may react specifically with amino acids having free polar groups at the ω position. Cadaverine can be produced from lysine, histamine from histidine, and tyramine from tyrosine.

Formation of Amides. When condensed with ammonia or amines, amino acid esters form acid amides:

$$\begin{array}{l} RCH-CONH_2 \\ \quad | \\ NH_2 \end{array}$$

Oxidation. Oxidizing agents easily decompose α-amino acids, forming the corresponding fatty acid with one less carbon number:

$$\begin{array}{l} RCH-\Psi OOH \\ \quad | \\ NH_2 \end{array} \xrightarrow{o} RCHO \xrightarrow{o} RCOOH + NH_3 + CO_2$$

Ninhydrin Reaction. A neutral solution of an amino acid will react with ninhydrin (triketohydrindene hydrate) by heating to cause oxidative decarboxylation. The central carbonyl of the triketone is reduced to an alcohol. This alcohol further reacts with ammonia formed from the amino acid and causes a red-purplish color. Since the reaction is quantitative, measurement of the optical density of the color produced is an indication of amino acid concentration. Imino acids, such as hydroxyproline and proline, develop a yellow color in the same type of reaction.

Maillard Reaction. In amino acids, the amino group tends to form condensation products with aldehydes. This reaction is regarded as the cause of the browning reaction when an amino acid and a sugar coexist. A characteristic flavor, useful in food preparations, is evolved along with the color in this reaction.

Ion-exchange Separations. Because amino acids are amphoteric, they behave as acids or bases, depending upon the pH of the solution. This makes it possible to adsorb amino acids dissolved in water on either a strong-acid cation exchange resin; or a strong-base anion exchange resin. The affinity varies with the amino acid and the solution pH. Ion-exchange resins are widely used in amino acid separations.

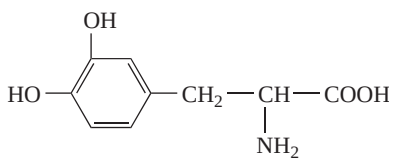
Production of Amino Acids. There are three means available for making (or separating) amino acids in large quantity lots: (1) extraction from natural protein; (2) fermentation; and (3) chemical synthesis. During the early investigations of amino acids, the first method was widely used and still applies to four amino acids. See Table 3.

L-Leucine is easily extracted in quantity from almost any type of vegetable protein hydrolyzates. Cystine is extracted from the human-hair hydrolyzate. L-Histidine is obtainable from the blood of animals, but future yields may stem from fermentation inasmuch as some artificial mutants of bacteria have been discovered. Gelatin is the prime source of L-hydroxyproline.

Natural amino acids, normally not contained in proteins, but which are effective in medicine, include citrulline, ornithine, and dihydroxyphenylalanine. These are not listed in Tables 2 and 3. Citrulline (Cit) with an isoelectric point of 5.9 was isolated by Koga in 1914; by Odake in 1914; and by Wada in 1930. It has the formula

$$\begin{array}{l} H_2NC-NH-(CH_2)_3CH-COOH \\ \quad || \qquad\qquad\quad | \\ \quad O \qquad\qquad\quad NH_2 \end{array}$$

Dihydroxyphenylalanine (Dopa) with an isoelectric point of 5.5 was isolated by Torquati in 1913; and by Guggenheim in 1913. It has the formula



Ornithine (Orn) with an isoelectric point of 9.7 was isolated by Riesser in 1906 from arginine. It has the formula

$$\begin{array}{l} CH_2-CH_2-CH_2-CH-COOH \\ \quad | \qquad\qquad\quad\quad | \\ \quad NH_2 \qquad\qquad\quad NH_2 \end{array}$$

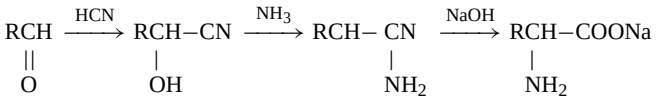
Fermentation Methods. Numerous microorganisms can synthesize the amino acids required to support their life from a simple carbon source and an inorganic nitrogen source, such as ammonium or nitrate salts, or nitrogen gas.

Japanese microbiologists, in 1956, first succeeded in developing industrial production of L-glutamic acid by a microbiological process. As of the present, nearly all common amino acids can be produced on a low cost industrial scale by fermentation. From microbiological studies, it has been ascertained that some microbial stains isolated from natural sources serve to excrete and accumulate a large amount of a particular amino acid in the cultural broth under carefully controlled conditions. The production of glutamic acid is produced by adding a selected bacterial strain and culturing aerobically for one to two days in a chemically defined medium which contains carbon sources, such as sugar or acetate, and nitrogen sources, such as ammonium salts. About 50% (wt) of the carbon sources can be converted to glutamate.

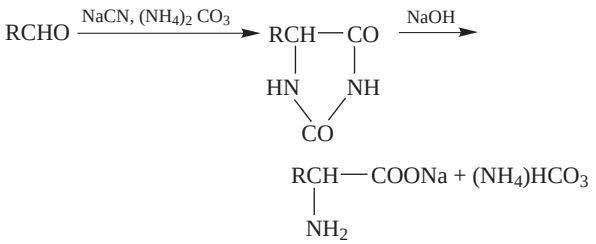
Genetic techniques have been used to improve the ability of microorganisms to accumulate amino acids. Several amino acids are manufactured from their direct precursors by the use of microbially produced enzymes. For example, bacterial L-aspartate β-carboxylase is used for the production of L-alanine from L-aspartic acid.

In isolating the amino acids from the fermentation broth, chromatographic separations using ion-exchange resins are the most important commercial method. Precipitation with compounds which yield insoluble salts with amino acids are also used. Purification is possible by crystallization through careful adjustment of the isoelectric point, at which point the amino acid is least soluble.

There are several laboratory-size methods for synthesizing amino acids, but few of these have been scaled up for industrial production. Glycine and DL-alanine are made by the Strecker synthesis, commencing with formaldehyde and acetaldehyde, respectively. In the Strecker synthesis, aldehydes react with hydrogen cyanide and excess ammonia to give amino nitriles which, in turn, are converted into α-amino acids upon hydrolysis.



The Hydantoin Process. Hydantoins are produced by reacting aldehydes with sodium cyanide and ammonium carbonate. Upon hydrolysis, α-amino acids will be yielded



The production of α-amino acids by chemical synthesis yields a mixture of DL forms. The D-form of glutamic acid has no flavor-enhancing properties and thus requires transformation into the optically active form insofar as monosodium glutamate is concerned. The three methods for separating the optical isomers are: (1) preferential inoculation method; (2) the diasteroisomer method; and (3) the acylase method.

AMITOSIS. Cell division without mitosis; a splitting of the cell into two parts without the previous duplication of chromosomes and segregation of the duplicated chromosomes into two separate groups. Formerly amitosis was thought to be the method of cell division for many of the simpler, one-celled forms of life. Improved techniques of microscopic study, however, have shown that there is some form of mitosis even in these simple forms. Today amitosis is recognized as a rare and abnormal form of cell division that produces cells with a limited survival.

AMMETER. See **Electrical Instruments**.

AMMINES. Dry ammonia gas reacts with dehydrated salts of some of the metals to form solid ammines. Ammines, upon warming, evolve ammonia, sometimes with final decomposition of the salt itself, in a manner analogous to the decomposition of certain hydrates. The ammines of chromium(III)(Cr^{3+}), cobalt(III), platinum(IV), and other metals have been studied in detail. Two series of ammines are shown in Fig. 1 the first is one in which the neutral ammonia group is replaced step by step by the negative nitro group (NO_2^-), the second is one in which the neutral ammonia group is replaced, step by step, by the neutral H_2O group.

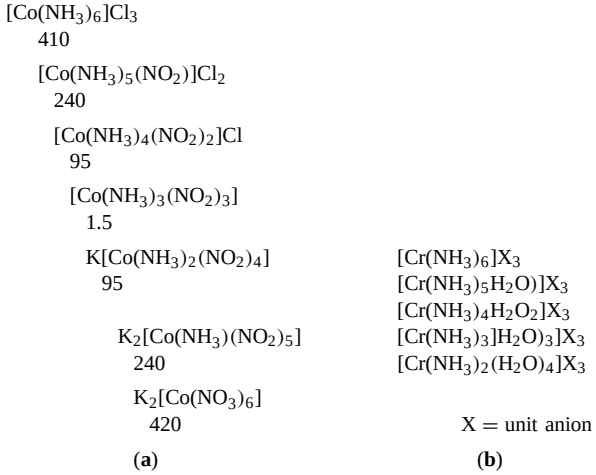

Fig. 1. Two series of ammines: (**a**) Square bracket contains the ion. The equivalent electrical conductivity is shown below each compound. The number of neutral groups, e.g., (NH_3), on metal, e.g., Co, is varied from 6 to 0. (**b**) The number of neutral groups is constant, but the groups are varied.

The neutral group of the complex may be replaced step by step by the following negative groups: Cl^-, Br^-, I^-, F^-, OH^-, NO_2^-, NO_3^-, CN^-, CNS^-, SO_4^{2-}, CO_3^{2-}, $C_2O_4^{2-}$; or by the following neutral groups: H_2O, NO, NO_2, SO_2, S,N_2H_4, H_2NOH, CO, C_2, H_5OH, C_6H_6. All neutral groups are of substances capable of independent existence.

In the ammines, trivalent metals, such as cobalt(III) and chromium(III) and iron(III), possess a coordination number of 6, this number being the sum of the unit replacements on the metal in the complex ion. Since a regular octahedron has six corners equidistant from the center, it is assumed that the metal occupies the center and each of the six replacing groups occupies a corner of a regular octahedron. Support for this assumption is offered by the x-ray examination of these ammines. When there is only one of the six groups replaced by a second group, as in $[Co(NH_3)_5(NO_2)]Cl_2$, and in $[Cr(NH_3)_5(H_2O)]X_3$ the octahedral placement of groups supplies only one form, but when two of the six groups are replaced by a second group, as in $[Co(NH_3)_4(NO_2)_2]Cl$, and in $[Cr(NH_3)_4(H_2O)_2]X_3$, two different octahedral corner arrangements are possible depending upon whether the two replacing groups are adjacent (cis-form) or opposite (trans-form). Two substances differing in physical properties and corresponding to these two forms are known. Further, when three divalent groups, e.g., $3C_2O_4^2A$ are present in the complex, two arrangements — not identical but mirror-images of each other — are possible. Two optically active substances are known in such cases corresponding to these two stereoisomeric forms.

Six is the ordinary coordination number for metallic ammines and similar complexes. Additional examples are $K_2[Pt(NH_3)_2(CN)_4]$, $[Ni(NH_3)_6]Cl_2$, $K_4[Fe(CN)_6]$, $K_3[Fe(CN_6)]$, $K_2[Fe(CN)_5(NO)]$, $K_2[SiF_6]$, $[Ca(NH_3)_6]Cl_2$.

But, for the elements boron, carbon, and nitrogen four is the coordination number, e.g., $[BH_4]Cl$, CH_4, $NH_4]Cl$, and in these substances the groups are assumed to occupy the corners of a regular tetrahedron; in $K_4Mo(CN)_8]$ and $[Ba(NH_3)_8]Cl_2$ the coordination number is eight, and the groups are assumed to occupy the corners of a cube.

AMMONIA. [CAS: 7664-41-7] Known since ancient times, ammonia, NH_3 has been commercially important for well over 100 years and has become the second largest chemical in terms of tonnage and the first chemical in value of production. The first practical plant of any magnitude was built in 1913. Worldwide production of NH_3 as of the early 1980s is estimated at 100 million metric tons per year or more, with the United States accounting for about 14% of the total production. A little over three-fourths of ammonia production in the United States is used for fertilizer, of which nearly one-third is for direct application. An estimated 5.5% of ammonia production is based in the manufacture of fibers and plastics intermediates.

Properties. At standard temperature and pressure, NH_3 is a colorless gas with a penetrating, pungent-sharp odor in small concentrations which, in heavy concentrations, produces a smothering sensation when inhaled. Formula weight is 17.03, mp $-77.7\,^{\circ}C$, bp $-33.35\,^{\circ}C$, and sp gr 0.817 (at $-79\,^{\circ}C$) and 0.617 (at $15\,^{\circ}C$). Ammonia is very soluble in water, a saturated solution containing approximately 45% NH_3 (weight) at the freezing temperature of the solution and about 30% (weight) at standard conditions. Ammonia dissolved in water forms a strongly alkaline solution of ammonium hydroxide, NH_4OH. The univalent radical NH_4^+ behaves in many respects like K^+ and Na^+ in vigorously reacting with acids to form salts. Ammonia is an excellent nonaqueous electrolytic solvent, its ionizing power approaching that of water. Ammonia burns with a greenish-yellow flame.

Ammonia derives its name from sal ammoniac, NH_4Cl, the latter material having been produced at the Temple of Jupiter Ammon (Libya) by distilling camel dung. During the Middle Ages, NH_3 was referred to as the spirits of hartshorn because it was produced by heating the hoofs and horns of oxen. The composition of ammonia was first established by Claude Louis Berthollet (France, ca. 1777). The first significant commercial source of NH_3 (during the 1880s) was its production as a byproduct in the making of manufactured gas through the destructive distillation of coal. See also **Coal Tar and Derivatives**.

Nitrogen fixation is a term assigned to the process of converting nitrogen in the air to nitrogen compounds. Although some bacteria in soil are capable of this process, N_2 as an ingredient of fertilizer is required for soils that are depleted by crop production. The production of synthetic NH_3 is the most important industrial nitrogen-fixation process. See also **Fertilizer**.

Synthesis of Ammonia

The first breakthrough in the large-scale synthesis of ammonia resulted from the work of Fritz Haber (Germany, 1913), who found that ammonia could be produced by the direct combination of two elements, nitrogen and hydrogen, ($N_2 + 3H_2 \rightleftharpoons 2NH_3$) in the presence of a catalyst (iron oxide with small quantities of cerium and chromium) at a relatively high temperature ($550\,^{\circ}C$) and under a pressure of about 200 atmospheres, representing difficult processing conditions for that era. Largely because of the urgent requirements for ammonia in the manufacture of explosives during World War I, the process was adapted for industrial-quality production by Karl Bosch, who received one-half of the 1931 Nobel Prize for chemistry in recognition of these achievements. Thereafter, many improved ammonia-synthesis systems, based on the Haber-Bosch process, were commercialized, using various operating conditions and synthesis-loop designs.

The principal features of an NH_3 synthesis process system are the converter designs, operating conditions, method of product recovery, and type of re-circulation equipment. Most current systems operate at or above the pressure used in the original Haber-Bosch process. Converter designs have either a single continuous catalyst bed, which may or may not have heat-exchange cooling for controlling reaction heat, or several catalyst beds with provision for temperature control between the beds.

Claude Process. The original Claude process was one of the first systems to use a high operating pressure (1000 atmospheres), achieving 40% conversion without recycling. This system used multiple converters in a series-parallel arrangement. The present Claude process[1] operates at 340–650 atmospheres, using a single converter with continuous catalyst-charged tubes externally cooled to remove the heat of reaction. Approximate hydrogen conversion is 30–34 mole percent per pass. The pressure is increased gradually to compensate for catalyst aging and loss in activity. Product recovery is by simple condensation in a water-cooled condenser. Nonreacted gas is recycled by compressor.

Casale Process. This is another high-pressure conversion system, using synthesis pressures of 450–600 atmospheres, which also permits hydrogen conversions in the 30 mole percent range. As in the Claude process, the high pressure allows NH_3 to be recovered from the converter effluent by water cooling. The Casale converter uses a single catalyst bed with internal heat-exchange surfaces. Reaction rate and temperature rise across the catalyst are controlled by the internal exchanger and retaining 2–3 mole percent NH_3 in the converter feed. An ejector is used to remove nonreacted gas. This eliminates the need for a mechanical recycle compressor, but requires high feed-gas pressures to supply the energy required for the ejector.

Low-Pressure Processes. Several systems use low synthesis pressures with hydrogen conversion below 30 mole percent and product recovery by water and refrigeration.

Synthesis-Gas-Production Processes. These processes were improved and developed as a result of changes in feedstock availability and economics. Before World War II, most NH_3 plants obtained H_2 by reacting coal or coke with steam in the water-gas process. A small number of plants used water electrolysis or coke-oven byproduct hydrogen. The subsequent low-cost availability of natural gas brought about steam-hydrocarbon reforming as the major source of H_2 for the NH_3 synthesis gas.

Partial oxidation processes to produce H_2 from natural gas and liquid hydrocarbons were also developed after World War II and accounted for 15% of the synthetic NH_3 capacity by 1962. The steam-hydrocarbon reforming process[2] was developed in 1930. In this process, methane was mixed with an excess of steam at atmospheric pressure, and the mixture reformed inside nickel-catalyst-filled alloy furnace tubes. The heat of reaction was supplied by externally heating the catalyst-filled tubes to about $871\,^{\circ}C$. Since the late 1950s, improvements in the tubular-reforming technology and metallurgy have brought about the utilization of high-pressure (>24 atmospheres) reforming, which cut synthesis-gas-compression costs and increased heat recovery. The first pressure reformer[3] was built in 1953. In addition, the higher pressures allowed improvements in the efficiency of synthesis-gas-purification systems. High-pressure steam-reforming technology also has been extended to cover heavier hydrocarbon gases, including propane, butane, reformer gases, and streams containing a high amount of olefins. In 1962, a process[4] for reforming straight-run liquid distillates (naphthas) was commercialized. This process is based on the use of an alkali oxide-promoted nickel catalyst[5] which permits reforming of desulfurized naphthas at low (~3.5:1) steam-to-carbon ratios, without significant carbon deposition problems.

Noncatalytic partial oxidation processes designed to produce H_2 from a wide range of hydrocarbon liquids, including heavy fuel oils, crudes, naphthas, coal tar, and pulverized bituminous coal, were commercialized in 1954[6] and 1956.[7] In both these processes, the hydrocarbon feed is oxidized and reformed in a refractory-lined pressure vessel. The required oxygen usually is supplied by an air separation plant from which nitrogen also is used as feed for the synthesis gas. The main differences between the two processes are in the reactor design, feeding method, burner design, and carbon and heat recovery. The partial oxidation processes and the steam-naphtha reforming process are favored in areas with short supplies of natural gas.

The source of nitrogen for the synthesis gas has always been air, either supplied directly from a liquid-air separation plant or by burning

a small amount of the hydrogen with air in the H_2 gas. The need for air separation plants has been eliminated in modern ammonia plants by use of secondary reforming, where residual methane from the primary reformer is adiabatically reformed with sufficient air to produce a 3:1 mole ratio hydrogen-nitrogen synthesis gas.

Most ammonia plants built since the early 1960s are in the 600–1500 short tons/day (540–1350 metric tons/day) range and are based on new integrated designs that have cut the cost of ammonia manufacture in half. The plants of the early 1960s, in fact, have reached the best combination in terms of plant overall efficiency and cost by combining all the separate units (e.g., synthesis-gas preparation, purification, and ammonia synthesis) in one single train. High-pressure reforming has reduced the synthesis-gas compression load and front end plant equipment size. This compactness in design has also led to increased plant size at reduced investment and operating costs.

Use of Multistage Centrifugal Compressors. One of the major factors contributing to the improved economics of ammonia plants is the application of multistage centrifugal compressors, which have replaced the reciprocating compressors traditionally used in the synthesis feed and recycle service. A single centrifugal compressor can do the job of several banks of reciprocating compressors, thus reducing equipment cost, floor space, supporting foundations, and maintenance.

The use of multistage centrifugal compressors was made possible by redesigning the synthesis loop to operate at low pressures (150–240 atmospheres) and by increasing plant capacity to above the compressor's minimum-flow restriction in order to obtain a reasonable compressor efficiency. (Most synthesis loops using reciprocating compressors had been operating at intermediate pressures of 300–350 atmospheres.) Centrifugal compressors capable of developing pressures up to 340 atmospheres already are being offered and used in some large-capacity (1000 short tons/day; 900 metric tons/day) plants, where the increasing compressor horsepower is partially offset by reduction of the refrigeration horsepower requirement.

An operating ammonia plant using the aforementioned improvements is shown schematically in Fig. 1. This plant[8] has a capacity of 1000 short tons/day (900 metric tons/day) and uses natural gas as feedstock. The plant can be divided into the following integrated-process sections: (a) synthesis-gas preparation; (b) synthesis-gas purification; and (c) compression and ammonia synthesis. A typical (Kellogg designed) ammonia plant is shown in Fig. 2.

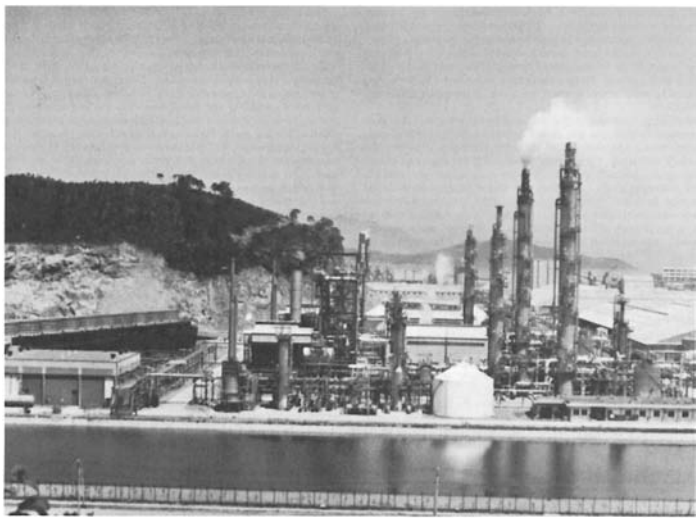

Fig. 2. Two 1000 short tons/day (900 metric tons/day) Kellogg-designed modern ammonia plants. (*M.W. Kellogg*.)

[8] Designed by The M.W. Kellogg Company, Houston, Texas, for which Kellogg received the 1967 Kirkpatrick Chemical Engineering Achievement Award.

Synthesis Gas Preparation. The desulfurized natural gas mixed with steam is fed to the primary reformer, where it is reacted with steam in nickel-catalyst-filled tubes to produce a major percentage of the hydrogen required. The principal reactions taking place are[9]

$$CH_4 + H_2O \rightleftharpoons CO + 3\ H_2 \quad (1)$$

$$\Delta H_{298} = 49.3 \text{ kcal/ mole}$$

$$CO + H_2Os\ CO_2 + H_2 \quad (2)$$

$$\Delta H_{298} = -9.8 \text{ kcal/mole}$$

Reaction (1) is the principal reforming reaction, and reaction (2) is the water-gas shift reaction. The net reactions are highly endothermic. The partially reformed gas leaves the primary reformer containing approximately 10% methane, on a mole dry-gas basis, at 27–34 atmospheres and up to 816 °C. The required heat of reaction is supplied by natural-gas-fired arch burners, which are designed to also burn purge and flash gases from the synthesis section. Waste heat from the primary reformer flue gas is recovered by generating high-pressure superheated steam, which along with waste-heat process boilers and an appended auxiliary boiler assure a steam system that is always in balance, while providing high-pressure steam to compressor turbine drivers and low-pressure steam to pump drivers. Further waste heat is recovered by preheating the natural-gas-steam feed mixture, steam-air for secondary reforming, and fuel.

The primary reforming step is followed by conversion of the residual methane to hydrogen and carbon oxides over a bed of high-temperature chrome and nickel catalysts in the secondary reformer. The secondary reforming step not only achieves a great degree of overall reforming economically possible, but also reduces fuel-gas input and overall reforming costs by shifting part of the required hydrocarbon conversion from the high-cost primary reformer to the lower-cost secondary reformer. It also permits an increase in the residual methane level at the primary effluent, which results in lower operating temperatures, reduced steam requirements, and milder tube-metal conditions.

Process waste-heat boilers then cool the reformed gas to about 371 °C while generating high-pressure steam. The cooled gas-stream mixture enters a two-stage shift converter. The purpose of shift conversion is to convert CO to CO_2 and produce an equivalent amount of H_2 by the reaction: $CO + H_2O \rightleftharpoons CO_2 + H_2$. Since the reaction rate in the shift converter is favored by high temperatures, but equilibrium is favored by low temperatures, two conversion stages, each with a different catalyst provide the optimum conditions for maximum CO shift. Gas from the shift converter is the raw synthesis gas, which, after purification, becomes the feed to the NH_3 synthesis section.

Purification of Synthesis Gas. This involves the removal of carbon oxides to prevent poisoning of the NH_3 catalyst. An absorption process is used to remove the bulk of the CO_2, followed by methanation of the residual carbon oxides in the methanator. Modern ammonia plants use a variety of CO_2-removal processes with effective absorbent solutions. The principal absorbent solutions currently in use are hot carbonates and ethanolamines. Other solutions used include methanol, acetone, liquid nitrogen, glycols, and other organic solvents.

The partially purified synthesis gas leaves the CO_2 absorber containing approximately 0.1% CO_2 and 0.5% CO. This gas is preheated at the methanator inlet by heat exchange with the synthesis-gas compressor interstage cooler and the primary-shift converter effluent and reacted over a nickel oxide catalyst bed in the methanator. The methanation reactions are highly exothermic and are equilibrium favored by low temperatures and high pressures.

$$CO + 3\ H_2 \rightleftharpoons CH_4 + H_2O$$

$$CO_2 + 4\ H_2 \rightleftharpoons CH_4 + 2\ H_2O$$

The methanator effluent is cooled by heat exchange with boiler feedwater and cooling water. The synthesis gas leaves the methanator containing less than 10 parts per million (ppm) of carbon oxides.

Compression and Synthesis. The purified synthesis gas, containing H_2 and N_2 in a 3:1 mole ratio and with an inert gas (methane and argon) content of about 1.3 mole percent, is delivered to the suction of the synthesis-gas compressor. Anhydrous ammonia is catalytically synthesized in the converter. The effluent from the converter, after taking off a small purge stream, is recycled for eventual conversion to ammonia. Reaction takes place at approximately 370–482 °C. Ammonia liquid, separated from the loop in the separator and from the purge, contains dissolved synthesis gas, which is released when the combined stream is flashed into the letdown drum. The flashed gas is then separated in the letdown drum and combined with the vapors from the purge separator to form a stream of purge fuel gases. Liquid ammonia in the letdown drum still contains some dissolved gases that must be disengaged. This liquid ammonia is let down to the refrigeration system where the dissolved gases are flashed and released to fuel. A centrifugal compressor is used to provide the refrigeration for the ammonia condensing. Ammonia product is withdrawn from the ammonia refrigeration system.

Modern Ammonia Plant. Since the development of the single train ammonia plant in the 1960s, many improvements have been made to reduce energy consumption. The plant of the 1980s has achieved striking results of reducing energy consumption by 20 to 30%—to less than 25 MMBTU(LHV)/ST (million Btus of low heating value fuel per short ton) of ammonia. This achievement represents a constant effort of development in seeking out more energy efficient design. Those developments have been centered around the 1960s basic process scheme with modifications to improve efficiency. Therefore, the basic process steps have not changed in any major way. The modern ammonia plants (after 1980) have incorporated energy-saving features, including: (1) more efficient furnace design to reduce fuel consumption, (2) more efficient drivers, compressors, and reduced power consumption, (3) low energy consumption in carbon dioxide removal system, (4) more efficient waste heat recovery and utilization, and (5) more efficient synthesis loop design, such as make-up gas drying, purge gas hydrogen recovery, and intercooled ammonia converter. The trend toward greater energy conservation is expected to continue.

Future Considerations in Ammonia Production. In addition to continued emphasis on energy efficiency, alternate feedstocks will continue to be a primary area of ammonia technology.

In the past, coal or heavy hydrocarbon feedstock ammonia plants were not economically competitive with plants where the feedstocks were light hydrocarbons (natural gas to naphtha). Because of changing economics, however, plants that can handle heavy hydrocarbon feedstock are now attracting increasing attention. In addition, the continuous development and improvement of partial oxidation processes at higher pressure have allowed reductions in equipment size and cost. Therefore, the alternate feedback ammonia plants based on a partial oxidation process may become economically competitive in the near future.

The ultimate goal of any ammonia process will be the direct fixation of nitrogen by reaction of water with air, $1.5H_2O + 0.5N_2 \rightleftharpoons NH_3 + 0.75O_2$. The theoretical energy requirement of the reaction is about 18 MMBTU/ST of ammonia. This feed energy requirement is the same as a natural gas feed ammonia plant. The major difference is that there is no short supply of water, air, and solar energy. However, the technology required for this route is not expected to be available any time soon. It is believed that, in the near future, ammonia plant designs will be based essentially on the present-day process with modifications to reduce energy consumption.

AMMONIUM CHLORIDE. [CAS: 12125-02-9] NH_4Cl, formula weight 53.50, white crystalline solid, decomposes at 350°, sublimes at 520 °C under controlled conditions, sp gr 1.52. Also known as *sal ammoniac*, the compound is soluble in H_2O and in aqueous solutions of NH_3; slightly soluble in methyl alcohol. Ammonium chloride is a high-tonnage chemical, finding uses as an ingredient of dry cell batteries, as a soldering flux, as a processing ingredient in textile printing and hide tanning, and as a starting material for the manufacture of other ammonium chemicals. The compound can be produced by neutralizing HCl with NH_3 gas or with liquid NH_4OH, evaporating the excess H_2O, followed by drying,

[9] Heats of reaction at 198 °K (25 °C), 1 atmosphere pressure, gaseous substances in ideal state.

crystallizing, and screening operations. The product also can be formed in the gaseous phase by the reacting of hydrogen chloride gas with NH_3. Ammonium chloride generally is not attractive as a source of nitrogen for fertilizers because of the build-up and damaging effects of chloride residuals in the soil. See also **Nitrogen**.

AMMONIUM COMPOUNDS. Several of the principal ammonium compounds are described in separate entries in this volume. See also **Ammonium Chloride**; **Ammonium Nitrate**; **Ammonium Phosphates**; and **Ammonium Sulfate**. The important aspects of several other ammonium compounds are summarized below.

Acetate: Ammonium acetate $NH_4C_2H_3O_2$, white solid, soluble, formed by reaction of ammonia or NH_4OH and acetic acid, reacts upon heating to yield acetamide.

Alum: Ammonium alums are those alums, such as aluminum ammonium sulfate $Al_2(NH_4)_2(SO_4)_4{\cdot}24H_2O$, ferric ammonium sulfate $Fe_2(NH_4)_2(SO_4)_4{\cdot}24H_2O$, chromium ammonium sulfate $Cr_2(NH_4)_2(SO_4)_4{\cdot}24H_2O$ where ammonium sulfate is crystallized with the heavier metal sulfate.

Benzoate: Ammonium benzoate $NH_4C_7H_5O_2$, white solid, soluble, formed by reaction of NH_4OH and benzoic acid. Used (1) as a food preservative, (2) in medicine.

Borate: Ammonium borate, ammonium tetraborate

$$(NH_4)_2B_4O_7{\cdot}4H_2O,$$

white solid, soluble, formed by reaction of NH_4OH and boric acid. Used (1) in fireproofing fabrics, (2) in medicine.

Bromide: Ammonium bromide NH_4Br white solid, soluble, sublimes at 542 °C, formed by reaction of NH_4OH and hydrobromic acid. Used in photography.

Carbonates: Ammonium carbonate, $(NH_4)_2CO_3$, volatile, white solid, soluble, formed by reaction of NH_4OH and CO_2 by crystallization from dilute alcohol, loses NH_3, CO_2, and H_2O at ordinary temperatures, rapidly at 58 °C; ammonium hydrogen carbonate, ammonium bicarbonate, ammonium acid carbonate NH_4HCO_3, white solid, soluble, formed by reaction of NH_4OH and excess CO_2. This salt is the important reactant in the ammonia soda process for converting sodium chloride in solution into sodium hydrogen carbonate solid.

Chloroplatinate: Ammonium chloroplatinate $(NH_4)_2PtCl_6$, yellow solid, insoluble, formed by reaction of soluble ammonium salt solutions and chloroplatinic acid. Used in the quantitative determination of ammonium.

Cobaltinitrite: Diammonium sodium cobaltinitrite,

$$(NH_4)_2NaCo(NO_2)_6{\cdot}H_2O$$

golden-yellow precipitate, formed by reaction of sodium cobaltinitrite solution in acetic acid with soluble ammonium salt solution. Used in the detection of ammonium.

Cyanate: Ammonium cyanate NH_4CNO, white solid, soluble, formed by fractional crystallization of potassium cyanate and ammonium sulfate (ammonium cyanate is soluble in alcohol), when heated changes into urea.

Dichromate: Ammonium dichromate $(NH_4)_2Cr_2O_7$, red solid, soluble, upon heating evolves nitrogen gas and leaves a green insoluble residue of chromic oxide.

Fluoride: Ammonium fluoride NH_4F, white solid, soluble, formed by reaction of NH_4OH and hydrofluoric acid, and then evaporating. Used (1) as an antiseptic in brewing, (2) in etching glass; ammonium hydrogen fluoride, ammonium bifluoride, ammonium acid fluoride NH_4F_2, white solid, soluble.

Iodide: Ammonium iodide NH_4I, white solid, soluble, formed by reaction of NH_4OH and hydriodic acid, and then evaporating. Used (1) in photography, (2) in medicine.

Linoleate: Ammonium linoleate $NH_4C_{18}H_{31}O_2$. Used (1) as an emulsifying agent, (2) as a detergent.

Nitrite: Ammonium nitrite NH_4NO_2 when ammonium sulfate or chloride and sodium or potassium nitrite are heated, the mixture behaves like ammonium nitrite in yielding nitrogen gas.

Oxalate: Ammonium oxalate $(NH_4)_2C_2O_4$, white solid, soluble, formed by reaction of NH_4OH and oxalic acid, and then evaporating. Used as a source of oxalate; ammonium binoxalate $NH_4HC_2O_4{\cdot}H_2O$, white solid, soluble.

Perchlorate: Ammonium perchlorate NH_4ClO_4, white solid, soluble, formed by reaction of NH_4OH and perchloric acid, and then evaporating. Used in explosives and pyrotechnics.

Periodate: Ammonium periodate NH_4IO_4, white solid, moderately soluble.

Persulfate: Ammonium persulfate $(NH_4)_2S_2O_8$, white solid, soluble, formed by electrolysis of ammonium sulfate under proper conditions. Used (1) as a bleaching and oxidizing agent, (2) in electroplating, (3) in photography.

Phosphomolybdate: Ammonium phosphomolybdate

$$(NH_4)_3PO_4{\cdot}12MoO_3$$

(or similar composition), yellow precipitate, soluble in alkalis, formed by excess ammonium molybdate and HNO_3 with soluble phosphate solution. Used as an important test for phosphate (similar product and reaction when arsenate replaces phosphate).

Salicylate: Ammonium salicylate $NH_4C_7H_5O_3$, white solid, soluble, formed by reaction of NH_4OH and salicylic acid, and then evaporating. Used in medicine.

Sulfide: Ammonium sulfide $(NH_4)_2S$, colorless to yellowish solution, formed by saturation with hydrogen sulfide of one-half of a solution of NH_4OH, and then mixing with the other half of the NH_4OH. Dissolves sulfur to form ammonium polysulfide, yellow solution. Used as a reagent in analytical chemistry; ammonium hydrogen sulfide, ammonium bisulfide, ammonium acid sulfide NH_4HS, colorless to yellowish solution, formed by saturation with H_2S of a solution of NH_4OH.

Tartrate: Ammonium tartrate $(NH_4)_2C_4H_4O_6$, white solid, moderately soluble, formed by reaction of NH_4OH and tartaric acid, and then evaporating. Used in the textile industry; ammonium hydrogen tartrate, ammonium bitartrate, ammonium acid tartrate $NH_4HC_4H_4O_6$, white solid, slightly soluble, formation sometimes used in detection of ammonium or tartrate.

Thiocyanate: Ammonium thiocyanate, ammonium sulfocyanide, ammonium rhodanate NH_4CNS, white solid, soluble, absorbs much heat on dissolving with consequent marked lowering of temperature, mp 150 °C, formed by boiling ammonium cyanate solution with sulfur, and then evaporating. Used (1) as a reagent for ferric, (2) in making cooling solutions, (3) to make thiourea.

Ammonium compounds liberate NH_3 gas when warmed with NaOH solution.

AMMONIUM HYDROXIDE. [CAS: 1336-21-6] NH_4OH, formula weight 35.05, exists only in the form of an aqueous solution. The compound is prepared by dissolving NH_3 in H_2O and usually is referred to in industrial trade as aqua ammonia. For industrial procurements, the concentration of NH_3 in solution is normally specified in terms of the specific gravity (degrees Baumé, °Be). Common concentrations are 20 °Be and 26 °Be. The former is equivalent to a sp gr of 0.933, or a concentration of about 17.8% NH_3 in solution; the latter is equivalent to a sp gr of 0.897, or a concentration of about 29.4% NH_3. These figures apply at a temperature of 60 °F (15.6 °C). Reagent grade NH_4OH usually contains approximately 58% NH_4OH (from 28 to 30% NH_3 in solution).

Ammonium hydroxide is one of the most useful forms in which to react NH_3 (becoming the NH_4^+ radical in solution) with other materials for the creation of ammonium salts and other ammonium and nitrogen-bearing chemicals. Ammonium hydroxide is a direct ingredient of many products, including saponifiers for oils and fats, deodorants, etching compounds, and cleaning and bleaching compounds. Because aqua ammonia is reasonably inexpensive and a strongly alkaline substance, it finds wide application as a neutralizing agent. See also **Nitrogen**.

AMMONIUM NITRATE. [CAS: 6484-52-2] NH_4NO_3, formula weight 80.05, colorless crystalline solid, occurs in two forms:

- α-NH_4NO_3, tetragonal crystals, stable between −16 °C and 32 °C, sp gr 1.66.
- β-NH_4NO_3, rhombic or monoclinic crystals, stable between 32 °C and 84 °C, sp gr 1.725.

The melting point generally ascribed to the alpha form is 169.6 °C, with decomposition occurring above 210 °C. Upon heating, ammonium nitrate yields nitrous oxide (N_2O) gas and can be used as an industrial source of that gas. Ammonium nitrate is soluble in H_2O, slightly soluble in ethyl alcohol, moderately soluble in methyl alcohol, and soluble in acetic acid solutions containing NH_3.

As shown in Fig. 1 in making ammonium nitrate on a large scale, NH_3, vaporized by waste steam from neutralizer, is sparged along with HNO_3

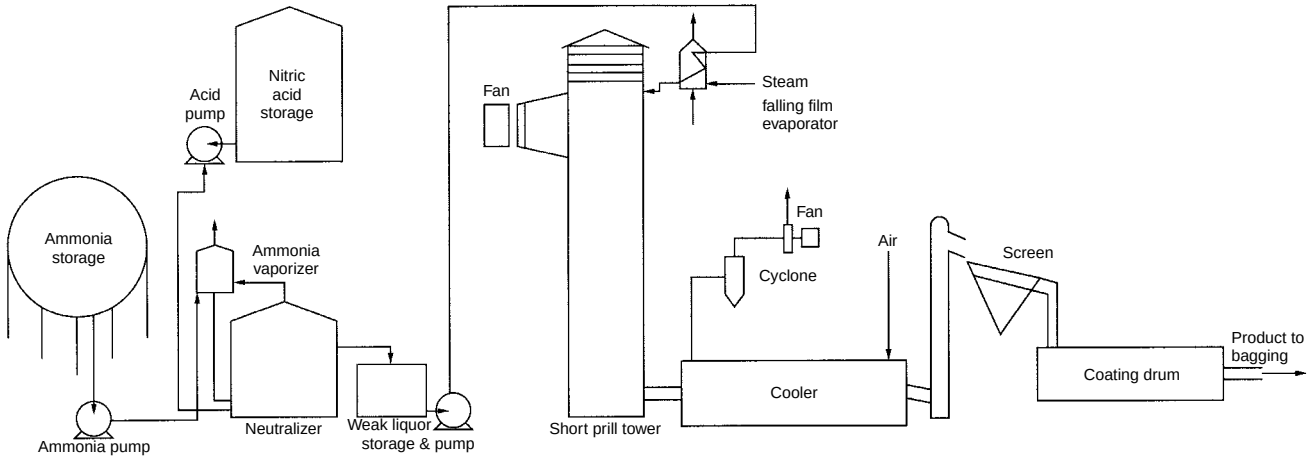

Fig. 1. Process for making ammonium nitrate on a large scale.

into the neutralizer. A ratio controller automatically maintains the proper proportions of NH_3 and acid. The heat of neutralization evaporates a part of the H_2O and gives a solution of 83% NH_4NO_3. Final evaporation to above 99% for agricultural prills or to approximately 96% for industrial prills is accomplished in a falling-film evaporator located at the top of the prilling tower. The resultant melt flows through spray nozzles and downward through the tower. Air is drawn upward by fans at the top of the tower. The melt is cooled sufficiently to solidify, forming round pellets or prills of the desired range of sizes. The prills are removed from the bottom of the tower and fed to a rotary cooler. Where industrial-type prills are produced, a pre-drier and drier precede the cooler. Fines from the rotary drums are collected in wet cyclones. This solution eventually is returned to the neutralizer. After cooling, the prills are screened to size and the over-and undersize particles are sent to a sump and returned to the neutralizer. Intermediate or product-size prills are dusted with a coating material, usually diatomaceous earth, in a rotary coating drum and sent to the bagging operation. The process can be adapted to other types of materials and mixtures of ammonium nitrate and other fertilizer materials. Mixtures include the incorporation of limestone and ammonium phosphates.

Ammonium nitrate is a very high tonnage industrial chemical, finding major applications in explosives and fertilizers, and additional uses in pyrotechnics, freezing mixtures (for obtaining low temperatures), as a slow-burning propellant for missiles (when formulated with other materials, including burning-rate catalysts), as an ingredient in rust inhibitors (especially for vapor-phase corrosion), and as a component of insecticides.

Amatol, an explosive developed by the British, is a mixture of ammonium nitrate and TNT. A special explosive for tree-trunk blasting consists of ammonium nitrate coated with TNT. In strip mining, an explosive consisting of ammonium nitrate and carbon black is used. The explosive ANFO is a mixture of ammonium nitrate and fuel oil. ANFO accounts for about 50% of the commercial explosives used in the United States. Slurry explosives consist of oxidizers (NH_4NO_3 and $NaNO_3$), fuels (coals, oils, aluminum, other carbonaceous materials), sensitizers (TNT, nitrostarch, and smokeless powder), and water mixed with a gelling agent to form a thick, viscous explosive with excellent water-resistant properties. Slurry explosives may be manufactured as cartridged units, or mixed on-site. Although Nobel introduced NH_4NO_3 into his dynamite formulations as early as 1875, the tremendous explosive power of the compound was not realized until the tragic Texas City, Texas disaster of 1947 when a shipload of NH_4NO_3 blew up while in harbor. See also **Explosive**.

As a fertilizer, NH_4NO_3 contains 35% nitrogen. Because of the explosive nature of the compound, precautions in handling are required. This danger can be minimized by introducing calcium carbonate into the mixture, reducing the effective nitrogen content of the product to 26%. In as much as NH_4NO_3 is highly hygroscopic, clay coatings and moisture-proof bags are means used to preclude spoilage in storage and transportation. See also **Fertilizer**; and **Nitrogen**.

AMMONIUM PHOSPHATES. There are two ammonium phosphates, both produced on a very high-tonnage scale.

Monoammonium phosphate, [CAS: 10124-31-9] $NH_4H_2PO_4$, white crystals, sp gr 1.803

Formula weight 115.04, N = 12.17%, P_2O_5 = 61.70%

Diammonium phosphate, CAS: 7783-28-0 $(NH_4)_2HPO_4$, white crystals, sp gr 1.619

Formula weight 132.07, N = 21.22%, P_2O_5 = 53.74%

Both compounds are soluble in H_2O; insoluble in alcohol or ether. A third compound, triammonium phosphate $(NH_4)_3PO_4$, does not exist under normal conditions because, upon formation, it immediately decomposes, losing NH_3 and reverting to one of the less alkaline forms.

Large quantities of the ammonium phosphates are used as fertilizers and in fertilizer formulations. The compounds furnish both nitrogen and phosphorus essential to plant growth. The compounds also are used as fire retardants in wood building materials, paper and fabric products, and in matches to prevent afterglow. Solutions of the ammonium phosphates sometimes are air dropped to retard forest fires, serving the double purpose of fire fighting and fertilizing the soil to accelerate new plant growth. The compounds are used in baking powder formulations, as nutrients in the production of yeast, as nutritional supplements in animal feeds, for controlling the acidity of dye baths, and as a source of phosphorus in certain kinds of ceramics.

Ammonium phosphates usually are manufactured by neutralizing phosphoric acid with NH_3. Control of the pH (acidity/alkalinity) determines which of the ammonium phosphates will be produced. Pure grades can be easily made by crystallization of solutions obtained from furnace grade phosphoric acid. Fertilizer grades, made from wet-process phosphoric acid, do not crystallize well and usually are prepared by a granulation technique. First, a highly concentrated solution or slurry is obtained by neutralization. Then the slurry is mixed with from 6× to 10× its weight of previously dried material, after which the mixture is dried in a rotary drier. The dry material is then screened to separate the desired product size. Oversize particles are crushed and mixed with fines from the screen operation and then returned to the granulation step where they act as nuclei for the production of further particles. Other ingredients often are added during the granulation of fertilizer grades. The ratio of nitrogen to phosphorus can be altered by the inclusion of ammonium nitrate, ammonium sulfate, or urea. Potassium salts sometimes are added to provide a 3-component fertilizer (N, P, K). A typical fertilizer grade diammonium phosphate will contain 18% N and 46% P_2O_5 (weight). See also **Fertilizer**; and **Nitrogen**.

There has been a trend toward the production of ammonium phosphates in powder form. Concentrated phosphoric acid is neutralized under pressure, and the heat of neutralization is used to remove the water in a spray tower. The powdered product then is collected at the bottom of the tower. Ammonium nitrate/ammonium phosphate combination products can be obtained either by neutralizing mixed nitric acid and phosphoric acid, or by the addition of ammonium phosphate to an ammonium nitrate melt.

AMMONIUM SULFATE. [CAS: 7783-20-2] $(NH_4)_2SO_4$, formula weight 132.14, colorless crystalline solid, decomposes above 513°C, sp gr 1.769. The compound is soluble in H_2O and insoluble in alcohol.

Ammonium sulfate is a high-tonnage industrial chemical, but frequently may be considered a byproduct as well as intended end-product of manufacture. Large quantities of ammonium sulfate result from a variety of industrial neutralization operations required for alleviation of stream pollution by free H_2SO_4. The ammonium sulfate so produced is not always recovered and marketed. A significant commercial source of $(NH_4)_2SO_4$ is its creation as a byproduct in the manufacture of caprolactam, which yields several tons of the compound per ton of caprolactam made. See also **Caprolactam**. Ammonium sulfate also is a byproduct of coke oven operations where the excess NH_3 formed is neutralized with H_2SO_4 to form $(NH_4)_2SO_4$. However, as a major fertilizer and ingredient of fertilizer formulations, additional production is required, largely depending upon the proximity of consumers to byproduct $NH_4)_2SO_4$ sources. In the Meresburg reaction, natural or byproduct gypsum is reacted with ammonium carbonate:

$$CaSO_4{\cdot}2H_2O + (NH_4)_2CO_3 \longrightarrow CaCO_3 + (NH_4)_2SO_4 + 2\ H_2O$$

The product is stable, free-flowing crystals. As a fertilizer, $(NH_4)_2SO_4$ has the advantage of adding sulfur to the soil as well as nitrogen. By weight, the compound contains 21% N and 24% S. Ammonium sulfate also is used in electric dry cell batteries, as a soldering liquid, as a fire retardant for fabrics and other products, and as a source of certain ammonium chemicals. See also **Fertilizer**; and **Nitrogen**.

AMMONOLYSIS. See **Amination**; and **Organic Chemistry**.

AMNESIA. A partial or total loss of memory of a temporary or permanent nature. The condition may result from a brain injury (see **Brain (Injury)**); or it may be symptomatic of a basic disorder of the mind. The condition is frequently associated with a dissociative reaction, but may also be evidenced in other psychoses resulting from stress, such as anxiety, phobic, obsessive-compulsive, and conversion reactions. *Retrograde amnesia* is an impaired ability to recall past events; *anterograde amnesia* is an impaired ability to learn new information; *confabulation*, sometimes associated with amnesia, is the fabrication of recent events.

In retrograde amnesia, anxiety over an event becomes so great that the individual is forced to forget it. In forgetting anxiety, the patient also forgets a multitude of necessary associations, including personal identity. Despite these shortcomings, the individual is often well oriented as to present time and place. The person simply cannot recall anything about the past. The patient's behavior appears so normal that the individual moves about freely without attracting undue notice. In some instances, the individual may wander restlessly from place to place, covering extensive regions in such travels.

Recovery of memory is sometimes spontaneous. Frequently, psychiatric help is required. This assistance may have to extend over an appreciable period. Upon regaining memory, the amnesic patient does not recall events that occurred during the period of amnesia. However, it is frequently possible to bring forth recent past events in considerable detail through hypnosis. This indicates that the loss of consciousness in dissociation is different from that of the delirious states. Patients who recover from delirium cannot recall experiences even when hypnotized.

In a dissociative reaction, there is an unconscious flight from situations of intolerable emotional stress. The reaction takes numerous forms, including some kinds of amnesia, sleep-walking, automatic writing, and the extremely rare "dual personality," in which two mental selves exist within the same body at the same time.

Amnesia may also occur as a consequence of Wernicke's encephalopathy. This condition is found in some chronic alcoholics whose diet is inadequate (frequently characterized by lack of thiamine). Neuronal degeneration results in mental confusion, disorders of eye movement (gaze), and ataxia. When the condition is left untreated, permanent neurological damage occurs, resulting in a severe impairment of memory known as Korsakoff's psychosis (or amnesic-confabulatory psychosis).

AMNIOCENTESIS. Extraction and analysis of some of the amniotic fluid from the sac surrounding the fetus. See **Embryo**.

AMNION. An accessory embryonic membrane common to reptiles, birds and mammals and a superficially similar structure found in some insects.

AMOEBA. A genus of one-celled animals in which the body consists of a naked mass of protoplasm and the organs of locomotion are temporary blunt protuberances of cytoplasm known as pseudopodia. The large fresh water form, *Amoeba proteus*, is a typical species. When seen under the microscope, this protozoan appears as a naked bit of protoplasm surrounded only by its thin plasma membrane (Fig. 1). When in an active state, it is constantly changing its shape as it moves about. This type of movement by means of pseudopodia is known as *amoeboid movement*. See also **Asexual Reproduction**; and **Cell (Biology)**.

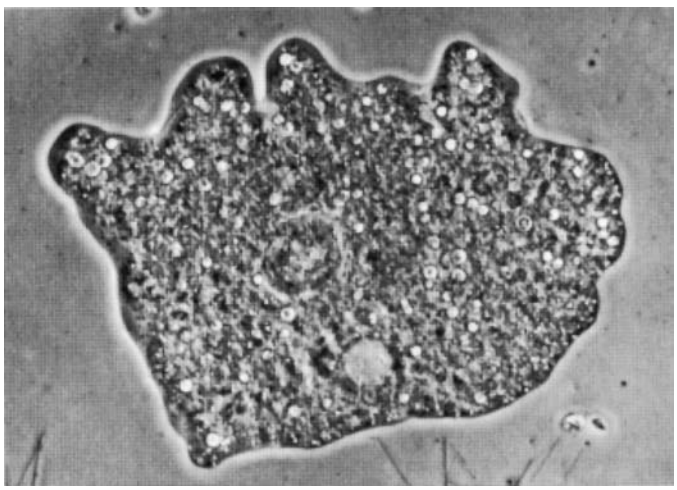

Fig. 1. Amoeba. (*A.M. Winchester*.)

AMOEBULAE. Spores of amoeboid form produced by some one-celled animals.

AMORPHOUS. As opposed to a crystalline substance which exhibits an orderly structure, the behavior of an amorphous substance is similar to a very viscous, inelastic liquid. Examples of amorphous substances include amber, glass, and pitch. An amorphous material may be regarded as a liquid of great viscosity and high rigidity, with physical properties the same an all directions (may be different for crystalline materials in different directions). Usually, upon heating, an amorphous solid gradually softens and acquires the characteristics of a liquid, but without a definite point of transition from solid to liquid state. In geology, an amorphous mineral lacks a crystalline structure, or has an internal arrangement so irregular that there is no characteristic external form. This does not preclude, however, the existence of any degree of order. The term amorphous is used in connection with amorphous graphite and amorphous peat, among other naturally occurring substances.

AMORPHOUS FROST. See **Meteorology**.

AMORPHOUS SKY. See **Clouds and Cloud Formation**.

AMOSITE. Amosite is a long-fiber gray or greenish asbestiform mineral related to the cummingtonite-grunerite series, and is of economic importance. It occurs within both regional and contact metamorphic rocks in the Republic of South Africa. The name *amosite* is a product of the initial letters of its occurrence at the Asbestos Mines of South Africa. See also **Asbestos**.

AMPERE'S LAW. This law of magnetostatics has been stated in a number of forms, one in terms of the magnetic field intensity produced by a current flowing in a thin conductor and another in terms of a line

integral about a closed path. The first form, which lacks exactness, is (refer to Fig. 1) that the magnitude of the magnetic field intensity dH at point P produced by a current of I amperes flowing through an element dl of a thin conducting wire at a distance r is

$$dH = \frac{I\,dl\cos\theta}{4\pi r^2}\text{amperes/meter}$$

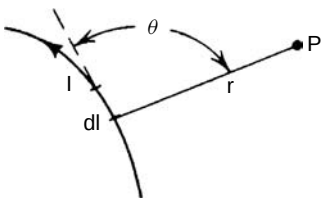

Fig. 1. Ampere's law in terms of magnetic field intensity.

The direction of dH is given by the right-hand screw rule. The total magnetic field intensity at P is the sum of the vector fields produced by all the conductor elements. The second form (refer to Fig. 2) is that the line integral of the magnetic field intensity around a closed path is equal to the total current which flows through any surface bounded by the closed path or $\phi H\cos\theta dl = I$. All units are in the meter-kilogram-second system.

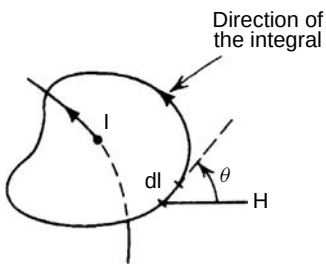

Fig. 2. Ampere's law in terms of a line integral about a closed path.

AMPERE'S RULE. The magnetic flux generated by a current in a wire encircles the current in the counterclockwise direction, if the current is approaching the observer.

AMPERE'S THEOREM. The magnetic field due to an electric current flowing in any circuit is equivalent at external points to that due to a simple magnetic shell, the bounding edge of which coincides with the conductor, and the strength of which is equal to the strength of the current.

AMPERE (Unit of Electric Current). Electric units, called "international," for current and resistance were introduced by the International Electrical Congress held in Chicago in 1893, and the definitions of the "international" ampere and the "international" ohm were confirmed by the International Conference of London in 1908.

Although it was already obvious on the occasion of the 8th CGPM (1933) that there was a unanimous desire to replace those "international" units by so-called "absolute" units, the official decision to abolish them was only taken by the 9th CGPM (1948), which adopted the ampere for the unit of electric current, following a definition proposed by the CIPM in 1946:

The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} *newton per meter of length.*

The expression "MKS unit of force" which occurs in the original text has been replaced here by "newton," the name adopted for this unit by the 9th CGPM (1948). Note that the effect of this definition is to fix the magnetic constant (permeability of vacuum) at exactly $4\pi \times 10^{-7}\mathrm{H}\cdot m^{-1}$.

See also **The International System of Units (SI)**; and **Units and Standards**.

AMPEROMETER. An instrument for the chemical analysis of electroreducible or oxidizable ions, molecules, or dissolved gases in solution. Included are the majority of metal ions and many organic substances that contain oxidizable or reducible groups. The range of concentration measurements of which the instrument is capable is from 0.01 to 1,000 ppm. This instrumental method is used for determining free available or total available chlorine, particularly in connection with water-chlorination control. In this application, the range of chlorine concentration is from 0 to 50 ppm. Free iodine also may be determined with an amperometer. The identification of unknown substances is by inference from noting the fixed potential between polarized microelectrode and reference electrode that causes oxidation or reduction of a given composition sought. Where identity is firmly established, the concentration also may be determined because the concentration is proportional to the diffusion-limited current that flows in the electrode circuit. In this latter respect, amperometry is similar to polarography. See also **Analysis (Chemical)**.

AMPHETAMINE. [CAS: 300-62-9] Also called methylphenethylamine; 1-phenyl-2-aminopropane; Benzedrine; formula $C_6H_5CH_2CH(NH_2)CH_3$; *ampheta mine* is a colorless, volatile liquid with a characteristic strong odor and slightly burning taste. Boils and commences decomposition at 200–203 °C. Low flash point, 26.7 °C. Soluble in alcohol and ether; slightly soluble in water. Amphetamine is the basis of a group of hallucinogenic, habit-forming drugs that affect the central nervous system. The drug also finds medical application, notably in appetite suppressants. It should be emphasized that administration of amphetamines for prolonged periods in connection with weight-reduction programs may lead to drug dependence. Professionals must pay particular attention to the possibility of persons obtaining amphetamines for nontherapeutic use or distribution to others.

AMPHIBIA. The frogs, toads, newts, salamanders and related forms. A class of the phylum *Chordata*. Since these animals live only in moist places their distribution is restricted and they are among the less familiar vertebrates.

The amphibians are distinguished by: (1) moist skin; (2) the absence of scales and claws; (3) a metamorphosis, undergone by most species during development, from an aquatic, gill-breathing larva to a semi-terrestrial, air-breathing adult stage. They evolved from lobe-finned fish in the Devonian and early amphibians are the ancestors of the amniotes.

While some of the salamanders are permanently aquatic and some of the tree frogs permanently terrestrial, most members of the class live near the water or in moist places and undergo the metamorphosis mentioned above.

English nomenclature within the class Amphibia is beset with semantic difficulties. There are three living orders. The first order, *Urodela* (*Caudata*), contains the animals commonly called salamanders and newts. Sometimes the term 'salamander' is used to refer to all members of the order, sometimes it is reserved for those in the family Salamandridae. The second order, *Anura* (*Salientia*), contains the ubiquitous frogs and toads. Again, the term 'frog' is sometimes used to apply to the whole order, but sometimes only to members of the large family Ranidae, and the term 'toad' seems to be applied indiscriminately to members of several families (e.g. American toad, family Bufonidae; spadefoot toad, family Pelobatidae; midwife toad, family Discoglossidae; clawed toad, family Pipidae). The common terms tree frog and tree toad add an extra dimension to these difficulties; there are simply not enough common English terms to cover all the taxonomic groups. The third order, *Gymnophiona* (*Apoda*), is much less well known with no common name in widespread use. 'Caecilian', derived from the name of the most diverse family, Caeciliidae, is the closest to a common name. In the current account, in an effort not to compound the difficulties, the standard scientific names of the orders will be used: *Urodela*, *Anura* and *Gymnophiona*. See also **Gymnophiona (Caecilians)**.

The inadequate English terminology probably reflects the relatively impoverished nature of the amphibian fauna in temperate Europe and North America, where much of the work on amphibian biology has occurred. A handful of species in the genera *Rana*, *Bufo*, *Ambystoma* and *Xenopus* account for the bulk of research work on amphibians, but between them they represent less than 0.5% of known species. In fact *Xenopus laevis*, a South African species, is most often cited in contemporary research publications. *Xenopus* is totally aquatic, a departure from the amphibian stereotype, and is used extensively because of the ease with which it is cultured in the laboratory. If we discount laboratory studies then the

remaining three genera, perhaps with the addition of *Triturus* and *Hyla*, tend to provide the basis for traditional understanding of the class, and all of them illustrate the classic life history involving aquatic larvae with metamorphosis into terrestrial adults. The common European frog *Rana temporaria* is an example. It has lungs, a moist skin and is ectothermic. It spends perhaps 10% of its life in water (as egg, tadpole and breeding adult), breeds in fresh water and completes its adult life within striking distance of fresh water. However, there is enormous diversity in the class, especially in the tropics, and several features of temperate amphibians, commonly regarded as characteristic, are by no means universal. See also **Caudata (Salamanders)**; and **Frogs and Toads**.

All the living amphibians, together with some extinct relatives, are placed in the subclass *Lissamphibia* (Table 1). There are also two extinct subclasses, the *Labyrinthodontia* and the *Lepospondyli*, containing early fossil amphibians, thought to have evolved from lobe-finned fish and to contain the ancestors of modern species. The changes, occupying millions of years, which occurred in the evolution of the primitive, largely aquatic amphibians into predominantly terrestrial animals are paralleled by the changes that occur in modern amphibians during metamorphosis, occupying a matter of days; however, although this implies recapitulation, it has been argued that metamorphosis evolved independently within modern amphibians and is not a reflection of the evolutionary process. See also **Terrestrialization (Precambrian-Devonian)**; and **Universal Tree of Life**.

Basic Design

Some idea of the changes necessary to produce a terrestrial from an aquatic animal can be obtained by comparing a modern anuran or urodele with a fish. This is a useful shorthand method of considering the changes that occurred during evolution from water to land. It must be remembered, however, that while some features (e.g. nervous, digestive and urinogenital systems) may be regarded as intermediate between fish and amniotes, for most systems a wide range of recent adaptations and specializations interfere with the concept. Furthermore many adult amphibian species are still aquatic.

Locomotion. Balance and locomotion on land would be aided by dorsoventral (as opposed to lateral) flattening and modification of fins into limbs. These need the support of strong bony appendicular and axial skeletons, together with appropriate musculature and nervous control. In the evolution of the amphibian skeleton from the primitive vertebrate notochord we see in the fossil record a progressive increase in articulation, strengthening of the intervertebral joints and ossification (replacement of cartilage by bone). The fish head is joined directly to the trunk, but in the amphibians there is a short neck, with a single atlas vertebra articulating with two occipital condyles on the skull. This increases flexibility, required both as an aid to quadrupedal locomotion and as compensation for the loss of aquatic buoyancy. A single sacral vertebra at the hip again serves to enhance flexibility. Differences in the locomotory adaptations of the three modern amphibian orders are reflected in differences in the vertebral column. The saltatory *Anura* have 6–10 vertebrae, the crawling *Urodela* 30–100 and the burrowing *Gymnophiona* have up to about 300. The *Anura* are particularly active and the loose linkage between the pectoral girdle and the axial skeleton, cushioned by muscles and tendons, helps to provide for flexibility, whilst the pelvic girdle is firmly attached to the vertebral column, providing a rigid base. Ribs, present in primitive tetrapods, are now reduced to tiny remnants fused to the vertebrae in most anurans. In the limbs, again there is diversity associated with lifestyle. The burrowing gymnophionans lack limbs altogether.

Nutrition. Finding and acquiring food in the terrestrial environment must have presented major challenges to the evolving amphibian. Olfaction and reception of vibrations, which work well in water, are replaced by vision as the dominant sensory mechanism for feeding in terrestrial species. The eye is enlarged, and this is accompanied by the reduction in the number of skull bones relative to the fish and early amphibians. Changes to the skull are further accentuated by modifications to accommodate jaw musculature. Prey capture is sometimes dependent on an extendible tongue, supported by a complex (and variable) hyoid apparatus. Swallowing is often accompanied by retraction of the eyes. Small pedicellate teeth also aid prey capture. These are structurally primitive and are not used in mastication. They are fused to the upper and lower jaw bones and capable of replacement if damaged. Most amphibians are opportunistic carnivores, predominantly nocturnal, but some have adapted to diurnal and crepuscular activity. Some are active hunters, others sit and wait for prey to appear.

Metabolism in amphibians is slow, especially in the Urodela, and they can survive for long periods without food, but when prey is available many species consume it voraciously, the distensible stomach acting as a food store. In periods of plenty, fat deposits are laid down, important for hibernating and aestivating animals.

TABLE 1. CLASSIFICATION OF THE AMPHIBIANS

Class *Amphibia*
Subclass *Labyrinthodontia*[a]
Order *Temnospondyli*[a]
Large, widespread and diverse group, with freshwater, terrestrial and perhaps marine forms (Devonian to Jurassic)
Order *Anthracosauria*[a]
Small, poorly known group (Mid Carboniferous to Late Permian)
Subclass *Lepospondyli*[a]
Order *Microsauria*[a]
Small group containing elongated, salamander-like animals with weak limbs (Early Carboniferous to Mid Permian)
Order *Aistopoda*[a]
Small group with aquatic, limbless snake-like members (Early Carboniferous to Mid Permian)
Order *Nectridea*[a]
Diverse pond-living group, adapted for swimming (Late Carboniferous to Mid Permian)
Subclass *Lissamphibia*
Order *Urodela*
Salamanders and newts (Late Jurassic to Recent)
Suborder *Kaurauroidea*[a]
Single monotypic genus, a small extinct salamander (Late Jurassic)
Suborder *Sirenoidea*
Single family of long-bodied aquatic salamanders with gills (Late Cretaceous to Recent)
Suborder *Cryptobranchoidea*
Two families, one with very large aquatic salamanders, the other with small mainly terrestrial members (early Tertiary to Recent)
Suborder *Salamandroidea*
Diverse group, including three extinct families, and the most widely known living families (Late Jurassic to Recent)
Order *Gymnophiona*
Caecilians (Late Jurassic to Recent)
Superorder *Salientia*
Order *Proanura*[a]
Contains a single monotypic frog-like genus (Early Triassic)
Order *Anura*
Frogs and toads (Mid Triassic to Recent)

[a] Extinct.

Coordination. There are well-developed endocrine and nervous systems in the amphibians. Most aquatic species and tadpoles possess a lateral line system. Audition, already well developed in fish, is developed for use in air and is especially significant in the anurans, most of which vocalize. Similarly, eye structure is modified for use in air, including the addition of eyelids. Eyes are reduced in gymnophionans. Chemical receptors are concentrated in the skin, as in fish. Olfaction is significant in larvae and in aquatic urodeles and there is a specialized sensory tentacle in gymnophionans.

Integument. The naked amphibian skin, a poor barrier to water loss, is sometimes regarded as a primitive aquatic feature, but it must be remembered that both the ancestral fish and amphibians possessed scales. It is, therefore, more likely to be a specialization, a compromise, catering for the interacting, often conflicting, demands of water retention, osmotic control, gaseous exchange, evaporative cooling and defence. The nature of the skin restricts the activity of most species to habitats in which water is readily available and provides one of the limitations to exploiting the terrestrial lifestyle.

The dermal scales seen in primitive amphibians have been lost (except in some gymnophionans) and the outer layer of the skin, the epidermis, is thin, facilitating gas exchange. Sometimes it is permeated with blood vessels, but normally these lie just below it, in the dermis. The dermis also accommodates alveolar glands that secrete mucus and maintain skin moisture, although some groups (e.g. *Bufo*) have dry skin. Glands are also present in aquatic species, where they provide lubrication for the body surface. Periodic sloughing of the skin accommodates growth of the body, which is indeterminate.

Respiration. Respiration requires radical alteration in an animal moving from the fish to amphibian lifestyle. In fish, the transfer of adequate supplies of oxygen into the blood from the surrounding water requires a large surface area for diffusion. This is supplied by the thin-walled, feathery, vascular gills that need to be protected, even in water. They are held in a protective gill chamber, while water is forced through them continuously, and a similar arrangement pertains in amphibian larvae and aquatic adults, although sometimes the gills remain external. Air has the advantage of a more plentiful and reliable oxygen supply, but the concomitant disadvantage of the need for a moist respiratory surface to transfer oxygen into the bloodstream. A variety of devices exist in terrestrial animals addressing this problem. Early amphibians had gills and lungs, but in modern species the problem is solved using three mechanisms.

First, most species, especially the active ones, possess lungs, but these are simple vascular sacs with little proliferation (Fig. 1). Second, and just as important for most species, is the entire surface of the vascularized skin. The lining of the buccal cavity provides a third respiratory surface in all three orders. Like the skin, this is lined by a thin cell layer, richly supplied with blood vessels; however, gas exchange is enhanced, relative to the skin, by the maintenance of a continuous flow of air through the buccal chamber acting as a force pump (Fig. 1). When the animal is at rest and the nares are open, air is drawn into the buccal chamber as the hyoid apparatus lowers the buccal floor. It is forced out again as the floor is raised. Air remains more or less static in the lungs during this process so that they contribute little towards gas exchange. As activity increases, the lungs are brought into play. At the end of a buccal floor downstroke the nares close, so that on the next upstroke air from the buccal cavity is forced into the lungs. On the succeeding downstroke, with the nares still closed, air is drawn out of the lungs again, to be discharged via the nares on the next upstroke. These actions can be observed in a resting amphibian: the buccal floor is in continuous movement, but occasionally the nares move, indicating use of the lungs.

As with other vertebrates, respiration is predominantly aerobic, but anaerobic generation of energy is used in support of intense short-term exercise. There is a possibility that large quantities of deoxyribonucleic acid (DNA), characteristic of some *Urodela*, may be an adaptation for survival in poorly oxygenated water.

Circulation. In all vertebrates, the respiratory system works in conjunction with the circulatory system in securing adequate tissue oxygen despite

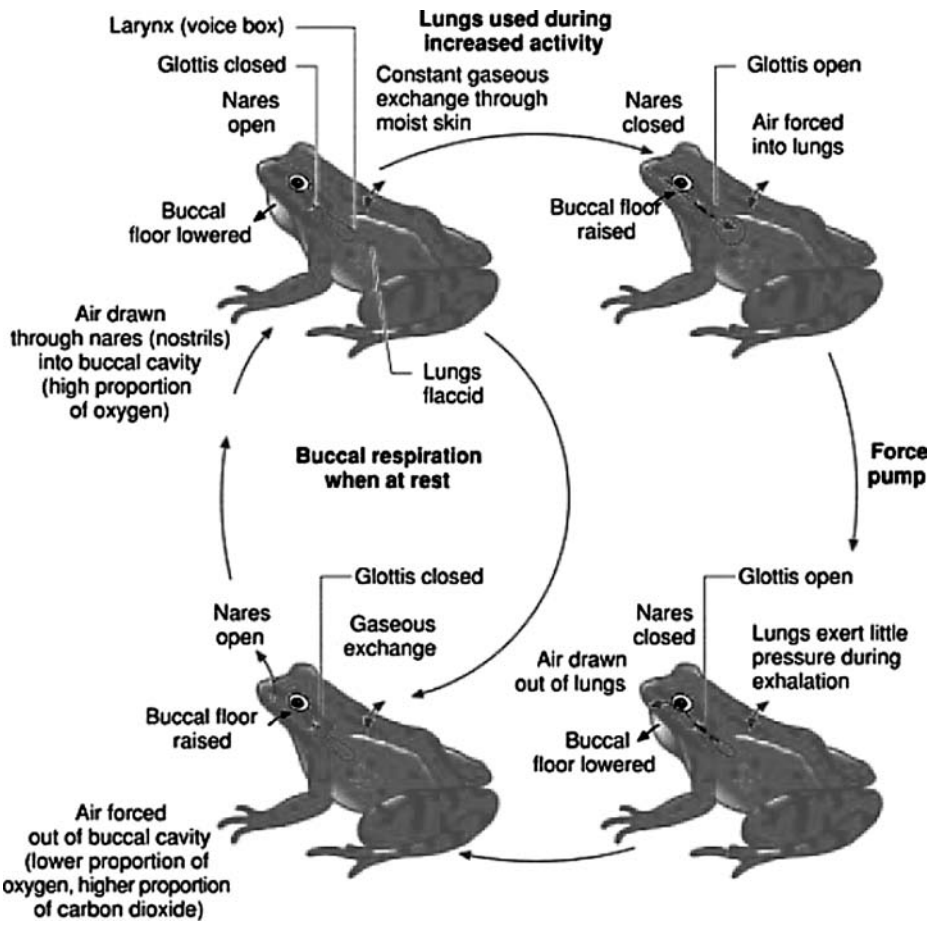

Fig. 1. Systems used in terrestrial amphibian respiration. Anuran outline illustrated, but similar mechanisms operate in all the living orders. (There is some overlap in the opening of nares and glottis so that during part of the lung ventilation cycle they are open simultaneously.)

changes in supply and demand. In fish, the heart pumps blood around what is essentially a single loop. The addition of lungs complicates the system. There are two atria, receiving blood separately from the lungs and from the rest of the body, respectively, but only one ventricle, which pumps mixed blood through the arterial system. In the more advanced tetrapods oxygenated and deoxygenated bloodstreams are divided into two completely separate loops. The incomplete separation in amphibians is probably associated with the relatively greater reliance in the amphibian on the skin and buccal cavity as respiratory surfaces, by comparison with amniotes.

The lymphatic system is well developed in amphibians, including lymph hearts absent in modern fish. The gymnophionans are particularly well endowed with lymph hearts, as many as 200 or more. There are fewer erythrocytes than in higher vertebrates and they are nucleated in amphibians. The largest erythrocytes of any vertebrate occur in *Amphiuma*, a North American urodele.

Water Relations and Excretion. Amphibians are composed of 70–80% body mass of water, and dissociation from water is perhaps the most obvious physiological problem facing them in moving from water to land. In an aquatic animal, the flux of water across permeable parts of the body surface is into the body, but this reverses in air. Furthermore, the kidneys are limited in their ability to concentrate urine and the amphibians require more water than other terrestrial vertebrates to excrete ions and nitrogenous wastes. Some of the integumentary adaptations have already been considered. Amphibians do not drink, but a number of additional mechanisms in various species include:

- the excretion of urea (and occasionally uric acid) instead of ammonia as the primary nitrogenous waste;
- accumulation of urea in the blood and bladder;
- storage of water in the urinary bladder (up to 50% of body mass) and in lymph sacs;
- the ability to take up water from wet surfaces via parts of the ventral epidermis;
- choice of appropriate microclimate;
- perhaps, above all, tolerance of water deficits and excretory excesses.

Amphibians are generally regarded as limited by saline environments, but once again there are exceptions, for example the Asian *Rana cancrivora*, which can live in an estuarine environment. Despite their adaptations, however, the ecological distribution of amphibians as a whole is affected mainly by the availability of fresh water.

Thermoregulation. Both fish and amphibians are ectothermic, i.e. their body temperatures depend more upon the ambient temperature than upon physiological processes. Air has a lower specific heat than water, so when they move to land amphibians are exposed to an increased environmental temperature variation: a daily range of as much as 30 °C (86 °F), in extreme cases. In the main they have adapted through increased limits of tolerance to change, sometimes including freezing. It may be that the costs of regulation, in terms of water loss, exposure to predation and energy expenditure, are prohibitive. Some species have, however, developed limited powers of thermal adjustment by evaporative cooling, dermal barriers, vasomotor and circulatory changes, metabolic heat production and behavioural adjustment of the microclimate, including burrowing. Species living in extreme environments may hibernate (or overwinter), in response to cold, or aestivate in response to drought, in some cases for as much as 65% of the year. Occasionally, repeated sloughing produces a cocoon composed of successive layers of skin and serving to reduce water loss during aestivation.

Reproduction. Amphibians are predominantly oviparous. The primitive amphibian reproductive mode, like fish, probably involved the laying of a large number, up to 15 000, of small noncleidoic eggs which were fertilized externally in water and had no parental care. There are, however, numerous variations, including direct development of the egg with no larval stage, ovoviparity (internal fertilization and egg development within one of the parents) and viviparity (with embryos receiving nutrition from the female oviduct). The gymnophionans all seem to have internal fertilization and oviparity or viviparity, the urodeles have predominantly (90%) internal fertilization, with both oviparity and viviparity represented, while the anurans depend predominantly (99%) on external fertilization. The efficiency of fertilization in anurans may be enhanced, relative to fish, by closer association between the sexes during amplexus. Most anurans are oviparous, but ovoviparity and viviparity are also represented.

The cleidoic egg is often regarded as the key development in the colonization of land. The noncleidoic eggs of amphibians do restrict colonization of land, but there are several species that lay them on land successfully. As with the fish, the excretory and genital systems are closely associated. The products of both systems are discharged through a common cloaca. Clutch size tends to be related to body size, and production of offspring by an individual female is determined by annual reproductive frequency and longevity. Longevity is poorly researched, especially in field populations. In captivity, there are records of individuals living for 55 years (*Cryptobranchus*). See also **Amphibia: Reproduction**.

Life History. Arguably the most fascinating aspect of amphibian biology is the diversity of reproductive modes and associated metamorphosis. The class presents a greater diversity of life history than any other vertebrate. There is a series of extreme modifications, with a trend towards terrestrial adaptation — a series of evolutionary 'experiments' using different mechanisms to those of their evolutionary siblings, the reptiles.

The three orders differ appreciably in their reproductive cycles. Gymnophionans tend to reproduce biennially. The urodeles reproduce seasonally or biennially, while the anurans range from continuous reproduction, with several clutches of eggs per year, to biennial reproduction. There are instances of parental care in all the orders. Amphibian eggs provide excellent subjects for embryological study, and the development of several species is well documented.

The breeding site can be located using a variety of cues during orientation, including auditory, olfactory, visual, geotactic and hydrostactic responses. Mate attraction by vocalization is common in the anurans, and is also known in some urodeles, which use low frequency sound.

The phenomenon of neoteny, the attainment of reproductive maturity in larvae, is known in nearly 50 species of urodele. Over half of these species are obligate neotenes, which reproduce only as larvae. Neoteny in urodeles probably results from delayed somatic development rather than precocious larval development.

Metamorphosis involves a series of abrupt changes involving structural, physiological, biochemical, ecological and behavioural processes. It is particularly marked in anurans (Fig. 2).

Diversity. There are about 4500 living species of amphibian, in about 430 genera and 40 families; 87% of the species belong to the *Anura*, 9% to the *Urodela* and the remaining 4% to the *Gymnophiona*. New species are constantly being found, especially in the relatively poorly studied tropical amphibian heartlands. Additionally, five extinct families and about 60 extinct genera have been described in the *Lissamphibia*, and more than 50 extinct families (over 200 extinct genera) in the two extinct subclasses. In the Paleozoic, amphibians were altogether more prominent than they are today, both in size and probably in abundance. There were some very large species including *Mastodontsaurus*, 4 m (13 ft) in length. Modern species reach a maximum length of 30 cm (12 inches) in the anurans (*Conraua goliath*), 160 cm (63 inches) in the urodeles (*Andrias japonicus*) and 150 cm (59 inches) in the gymnophionans (*Caecilia thompsoni*).

Amphibians share ectothermy with the reptiles and both are essentially tropical groups. Approximately 80% of known amphibian species, especially the anurans and the gymnophionans, occur in the tropics. The Urodela, largely restricted to temperate climates, are an exception. Nevertheless, there are amphibians in all climatic zones and on all continents (except Antarctica) and on most continental islands. A diversity of morphological types inhabit aquatic systems, tropical and temperate forests, grasslands and deserts. See also **Reptilia (Reptiles)**.

As might be anticipated, the largest group, the Anura, is also the most diverse in lifestyle and the most widespread. It includes entirely aquatic species, such as *Xenopus*, and entirely terrestrial species, like *Arthroleptis*, that lay eggs on land, the young emerging as fully-formed juvenile frogs. Different species live as subterranean, fossorial, cursorial and arboreal animals. The largest single amphibian (and indeed vertebrate) genus is *Eleutherodactylus*, a neotropical anuran, with over 400 named species. The urodeles are more restricted, both geographically and taxonomically. They occur mainly on the Laurasian landmass, the North Temperate Zone, except for recent incursion into the American tropics by the plethodontids. The gymnophionans are all either aquatic or burrowing animals confined to the tropics, mainly on Gondwanan landmasses, including such fragments as the Seychelles.

Ecology. Most amphibians utilize both aquatic and terrestrial habitats, and typically the egg and larval phases occur in water, the adult phase on land. In this way they are able to exploit more of the available resources

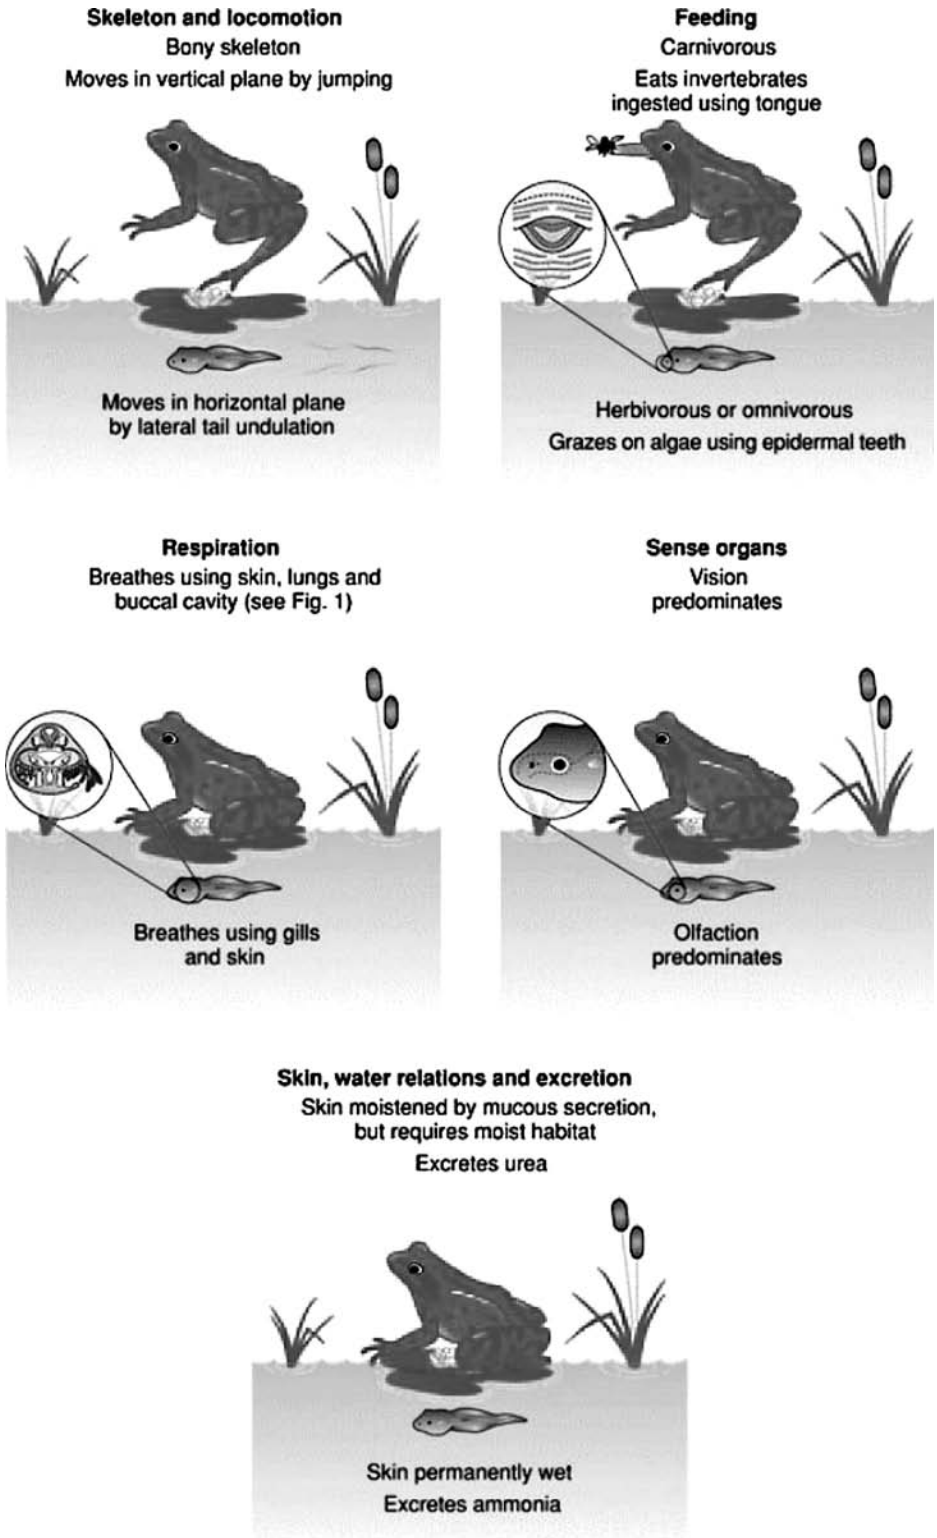

Fig. 2. Some of the radical changes occurring during the metamorphosis of an anuaran, Rana temporaria

in an area than would otherwise be possible; in other words, they have a wider ecological niche than an animal living in only one habitat. While the tadpoles exploit the rapid vegetation or planktonic growth in shallow pools, their parents exploit an array of terrestrial invertebrates. If, as is frequently the case, males and females are of different sizes, they tend to eat different food organisms and so further increase the efficiency of habitat exploitation. The process of niche expansion may go even further. Some groups, such as the African *Hyperolius*, exhibit polychromatism (diversity of color). Individuals of different colour tend to dispose themselves in those parts of the habitat in which they are best camouflaged, again promoting efficient use of habitat resources.

As in other animal groups, specialists (K-selected) and generalists (r-selected) can be recognized among the amphibians, the former predominating in stable environments, the latter in unstable environments, including those disturbed by humans. Specialist species tend to have relatively late sexual maturity, multiple clutches, larger eggs, slower development and parental care, while generalists show the opposite correlates. Anurans with aquatic larvae undergoing rapid development tend towards the generalist end of the spectrum.

Some species function as metapopulations, survival of the species in a given area depending upon periodic recolonization of breeding sites from adjacent populations. An understanding of population regulation in

amphibians is especially difficult because of the two phases of the life cycle of most species. In some cases, limitation may occur in the aquatic phase; sometimes in the terrestrial phase. The breeding season of species using aquatic habitat is usually timed to coincide with a period of high biological productivity and there is often a wide niche overlap between species, but still relatively little competition. In these situations, predation may be a major factor in population regulation. The relatively unprotected eggs and larvae are particularly vulnerable. Adult defensive mechanisms include jumping, chemical defense, warning display, tail autonomy, aposematic coloration, mimicry and cryptic coloration. Abiotic regulation, caused by drought, may occur in species using ephemeral pools. Intraspecific and interspecific competition can be intense in restricted aquatic habitats. Both exploitation (the use of common resources) and interference (of one species or individual by another) have been recognized, the latter sometimes mediated by an alga, *Prototheca*. This is carried in the tadpole gut and passed between individuals by coprophagy. It acts as a growth inhibitor but has a disproportionate effect on small tadpoles.

Amphibian distribution is determined by the response of each species to its environmental constraints, especially water, together with the effect of history. Historical constraints include the interplay of plate tectonics and climate and, more recently, the impact of human beings. The most serious human threat is habitat destruction, especially forest destruction and drainage. Species with specialized habitats and small ranges are especially vulnerable. Serious impact on amphibian populations has also been documented as a result of the use of pesticides and fertilizers, from acid rain and other pollutants (some of which induce deformity rather than mortality), ozone depletion and associated ultraviolet irradiation, human consumption, scientific collection and the pet trade. Decline of populations has even been recorded from apparently pristine habitats, the causes of which are still unknown.

Amphibians provide some benefit to agriculture by eating crop pests, and to medical hygiene by vector control, although their quantitative effects are not well studied. Efforts to conserve species are being made, mainly through measures aimed at individual threatened species, but, as with research efforts, they tend to be most prominent in those parts of the world where amphibian diversity is low.

Fossil History. The first amphibians, primitive tetrapods, descended from freshwater bony fishes (class Osteichthyes) during the Devonian period, about 400 million years ago. The best known early amphibian fossil is *Ichthyostega*, found in Greenland from the late Devonian. It had a bony internal skeleton, including primitive vertebrae, bony dermal plates, lungs and an arrangement permitting the use of the nostrils for breathing. The actual group of fossil fish ancestor is unresolved, the subject of contemporary debate. One school of thought, basing conclusions on the fossil record, favors the crossopterygian fish (represented today only by the coelacanths). Another school, using homologies derived from studying the comparative morphology of living species, believes the ancient dipnoans (represented today by lungfishes) provide the most likely tetrapod ancestor. Both had an important prerequisite for movement on land, fins with a bony main axis. It is possible that periods of drought during the Devonian may have given a selective advantage to species with the ability to survive on land, even briefly, while struggling between freshwater pools. Many of the dramatic changes reviewed under Basic Design, above, would be required, even for brief excursions on land. See also **Fossil Record**; **Osteichthyes (Bony Fishes)**; and **Terrestrialization (Precambrian–Devonian)**.

Following their emergence, the early amphibians underwent extensive adaptive radiation during 100 million years or so in the Carboniferous, Permian and Triassic periods, with steadily increasing levels of exploitation of the terrestrial environment, although there were still groups that lived in water. The groups represented by fossils are shown in Figure 3. Their taxonomy is based especially on the details of the vertebral column and the patterns of the skull bones. Each of the labyrinthodont orders (to which *Ichthyostega* belonged) contained several suborders. Both subclasses contain a wide variety of forms and lifestyles, including snake-like and eel-like species, species with horned skulls, specialized aquatic fish-eating species, as well as generalized aquatic and terrestrial forms. Competition with fish was augmented gradually, from the mid-Carboniferous, by competition with the evolving reptiles. A predatory mode of life predominated, as it does today, with fish and invertebrates, as well as smaller species of amphibians, as prey.

Phylogeny. The three orders of modern amphibians and some extinct forms are commonly grouped together in the third amphibian subclass,

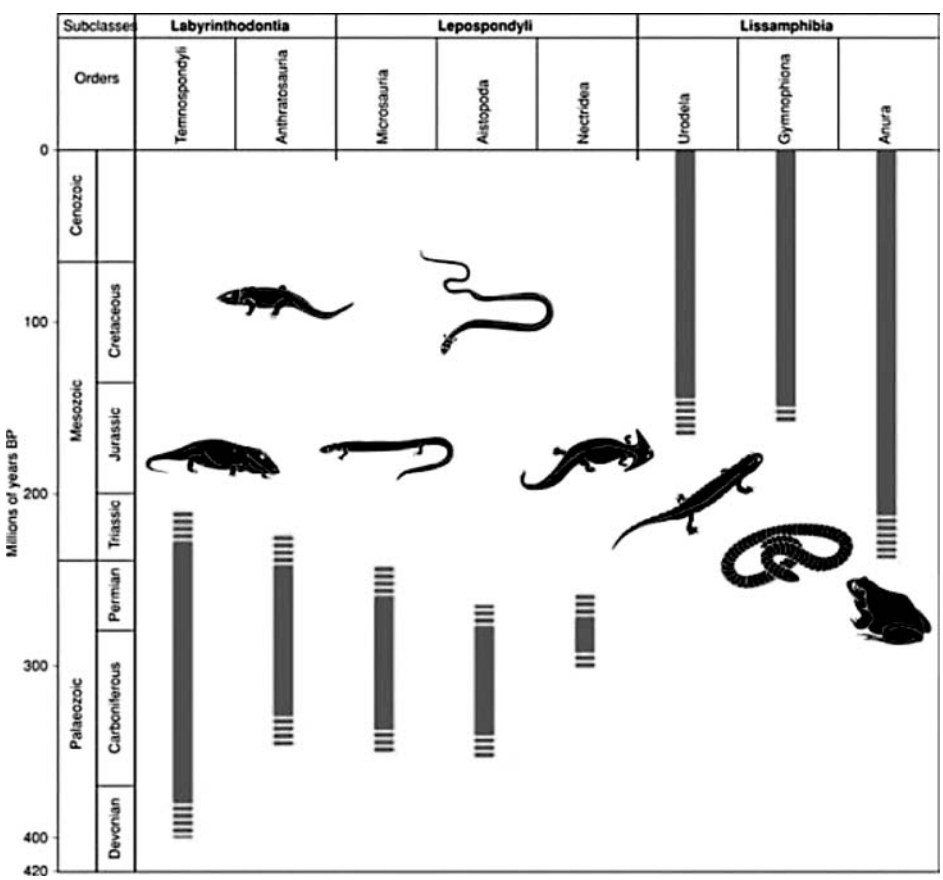

Fig. 3. Fossil history of the Amphibia

the *Lissamphibia*. Here again, however, as with the origin of the tetrapods, there is serious contemporary debate, with no fewer than four separate sets of opinions:

- that the subclass *Lissamphibia* is monophyletic, with one common ancestor;
- that the *Anura* evolved separately from the *Urodela* and the *Gymnophiona*;
- that the *Gymnophiona* evolved separately from the other two orders;
- that the *Lissamphibia* (Table 1) is polyphyletic, each of the three orders with a separate origin among the early amphibians.

The most commonly cited ancestors are the labyrinthodont order *Temnospondyli* (for all orders), and the lepospondylian order *Microsauria* (for the *Urodela* and *Gymnophiona*) (Fig. 3).

AMPHIBIA REPRODUCTION. Living amphibians form a monophyletic group, the members of which are classified into three subgroups. Most species-rich and widespread geographically is the *Anura*, to which belong the tail-less frogs and toads. The *Caudata* contains the newts and salamanders, tailed amphibians that are limited largely to the northern hemisphere. Members of the *Gymnophiona* are found only in the New and Old World tropics. Commonly known as caecilians, these limbless, burrowing amphibians are poorly understood. See also **Amphibia; Caudata (Salamanders); Frogs and Toads**; and **Gymnophiona (Caecilians)**.

As reviewed here, many aspects of the reproductive biology of these three subgroups are shared, both among one another and with other vertebrates. However, other aspects are far more varied, making the modes of reproduction in amphibians the most diverse of all tetrapod (or ancestrally four-limbed) vertebrates.

Gonads

At its most basic level, the reproductive system of amphibians is similar to that of other vertebrates, indicating both evolutionary relatedness and descent from a common ancestor. The anterior lobe of the pituitary gland, lying below the hypothalamus of the floor of the brain, produces glycoprotein hormones, known as gonadotrophins, that stimulate the gonads to produce gametes (sex cells) and a variety of steroid hormones. The sexes are separate in amphibians. Male testes produce sperm and androgenic steroids, the best known of which are testosterone and dihydrotestosterone. Female ovaries produce yolk-rich eggs, and oestrogen and progestin hormones.

In amphibians, sperm are produced as clones, each clone derived from a single, undifferentiated sperm stem cell that subsequently divides by meiosis, and which is located in a cyst-like structure. Similar cysts are found in the testes of fishes; truly tubular sites of sperm formation are present in reptiles, birds and mammals. The ovaries of females are hollow structures, covered by a germinal epithelium from which eggs are derived by meiosis. Both testes and ovaries are associated with fat deposits that provide the energy needed for gamete production.

In both sexes, ducts connect the gonads to the cloaca, which is a common exit for gametes, faeces and urine. In amphibians that lay eggs (the majority of taxa), the oviduct of the female produces secretions that form protective layers of jelly around each egg. In anurans, these jelly layers also are needed for successful fertilization. The eggs of amphibians lack shells and so are sensitive to desiccation.

Steroid hormones produced by the gonads play important roles in gamete formation (or gametogenesis). For example, progestins stimulate developing eggs to accumulate yolk precursors from the female's blood, which themselves are produced by her liver under the influence of oestrogen. In addition, steroid hormones have actions on non-gonadal structures involved in reproduction, these effects being best studied in males. Thus, adequate levels of androgenic steroids are necessary for male anurans to develop the larynxes (voice boxes) needed for vocalization, and for male caudates to develop skin glands that are used during courtship. In addition, these steroids affect nerve centers in the brain to regulate the sexual behavior patterns of males. They do this by interacting with a small, peptide hormone, known as vasotocin, which is found in both the hypothalamus and the posterior lobe of the pituitary gland.

Gametes

As is typical for almost all animals, male amphibians produce many, small, mobile sperm, whereas females produce fewer, larger, immobile eggs. To the extent that the optimal time for successful breeding varies seasonally, natural selection has produced patterns of gametogenesis that vary greatly in their own timing. See also **Reproduction in Vertebrates: Overview**.

For taxa that live in relatively aseasonal environments (e.g. certain tropical regions), gametes may be produced more or less continuously. In environments where seasonality is more pronounced, gametogenesis more often is discontinuous. A common pattern that is present in taxa of the temperate zone is for mature sperm and eggs to be formed between, not during, consecutive breeding seasons (with gametes held in the gonads until their use). In these taxa there is a clear dissociation in time between gamete maturation and sexual activity. See also **Gamete**.

Mating and Fertilization

Sexual activity is conspicuous in many anurans due to the vocalizations that males of most taxa produce to attract females. In anurans that live in noisy environments, such as close to waterfalls, males may use visual signals to attract mates, e.g., stereotyped waving movements of their limbs. Mating involves close physical contact between the sexes, with the male often clasping the female with his forelimbs in a posture known as amplexus.

Fertilization is external in almost all anurans, and mating partners release their gametes more or less synchronously either into water or, less often, into terrestrial habitats that are sufficiently damp. In the very few taxa that practice internal fertilization, males and females press their cloacas together to achieve sperm transfer. An exception is the North American tailed frog, in which an extension of the male's cloaca (his 'tail', although it is not a true tail) is used in the same way as a mammalian penis.

Mating in caudates often occurs in relatively inaccessible habitats, such as murky ponds or in the litter on the floors of damp forests; mating seldom is seen in the wild. Courtship by the male involves provision of a great deal of visual, tactile and chemical stimulation to the female; sexual scents often are produced by specialized skin glands that are present only in males (typically on their chins or cheeks).

Fertilization is internal in most caudates, with sperm transfer achieved by means of a sperm-capped packet, or spermatophore, that the male places on the substrate. A female whose sexual motivation has been increased by the male's courtship actions then retrieves the spermatophore in her cloaca. Sperm are stored in specialized tubules in the female's cloaca, known as spermathecae, until she is ready to lay her eggs. In a few taxa of internally fertilizing caudates, females retain fertilized eggs in their reproductive tracts, later giving birth to live young. See also **Caudata (Salamanders)**.

Mating has been described for just a handful of gymnophionans, and seems to involve a lot of physical contact. Fertilization is internal, with the male transferring sperm directly into the female's cloaca using a penis-like modification of his own cloaca known as a phallodeum. In many caecilians, females then lay fertilized eggs; in others, eggs are retained in the female's

reproductive tract and live young are produced some time later. See also **Gymnophiona (Caecilians)**.

Sexual Selection

Females invest far more time and energy in the production of eggs than males invest in sperm in most animals and, as a consequence, the availability of females carrying eggs for fertilization often limits male reproductive success. This basic asymmetry between the sexes explains why males typically compete with one another for mating opportunities, whereas females typically are choosy about which males they accept as mates. As first realized by Charles Darwin, both competition and choice can generate what he termed sexual selection on those male traits that are most advantageous in the struggle to reproduce.

In many anurans, vocalizations produced by males serve both to attract females (and sometimes predators, too) and repel same-sex rivals. In addition, males may engage in physical combat for calling sites, breeding territories preferred by females or females directly; in some South American gladiator frogs, fights between males can be lethal. Females often prefer those males who produce calls that are the loudest, fastest, longest or deepest in pitch. In some taxa, males producing these preferred calls also sire offspring that are superior in terms of growth rates or survival. Thus, choosy females may obtain genetic benefits for their young. See also **Frogs and Toads**.

Because the production of attractive vocalizations is expensive energetically, only males with sufficient energy reserves are able to call. However, males that are unable to vocalize still attempt to mate, often by lurking close to calling males and then intercepting females that are attracted. Known as satellites, these non-calling males essentially parasitize the mating efforts of their noisy neighbors.

Competition for mating opportunities can be intense in caudates, too. Males may fight for females directly or for breeding territories that females visit for mating; fights can have damaging, and sometimes lethal, consequences. In addition, unpaired males may interfere in ongoing sexual encounters, often by mimicking behavior patterns exhibited by responsive females in an effort to both avoid detection and steal inseminations. Female caudates often prefer males that produce the most stimulating courtship displays, but whether females or their young gain benefits from such choosiness is not known. Curiously, male caudates of many taxa also are choosy, preferring larger females as mates. Because such females carry more eggs for fertilization than their smaller sisters, choosy males may sire more young. See also **Caudata (Salamanders)**.

Sexual selection has yet to be studied in gymnophionans. But internal fertilization suggests the possibility that, if females mate with multiple partners, then sperm from different males may compete for fertilizations within female reproductive tracts. Such sperm competition also may occur in the many caudates and very few anurans that practice internal fertilization. Another possibility with internal fertilization is that females may selectively store or use the sperm of some mating partners but not others, resulting in a rather cryptic form of female choice. See also **Gymnophiona (Caecilians)**.

Of course, sperm competition need not be limited to taxa with internal fertilization. As in many fishes, unpaired male anurans and caudates in taxa that fertilize externally may liberate their sperm close to spawning pairs, and perhaps obtain some sneaky fertilizations as a result.

Sex Determination

Most amphibian taxa lack sex chromosomes that are distinct morphologically, but experimental evidence suggests strongly that sex is determined genetically. At least in nature, environmental factors such as temperature probably have little or no influence on an individual's sex.

In terms of differentiation of the embryological gonad into either a testis or an ovary (with associated ducts), our best working hypothesis is that the production of sex-specific hormones during early development results in sex-specific differentiation. This also appears to be true for certain non-gonadal structures involved in reproduction, such as the larynx of male anurans. See also **Sex Hormones in Vertebrates**.

Hormones produced by the thyroid gland can also influence gonadal differentiation under experimental conditions. In amphibians, thyroid hormones are best known for stimulating the process of metamorphosis by which larvae are transformed into juveniles in the typical, indirect life cycle of these animals.

Care of Embryo and Young

From the likely ancestral pattern of external fertilization with no further parental investment and the later metamorphosis of a free-living larva into a juvenile, natural selection has produced diverse modes of parental care in living amphibians.

For taxa with internal fertilization, males literally are free to leave females 'holding the babies' after mating. Not surprisingly, parental care in those caudates that practice internal fertilization appears to be limited to mothers, assuming that any care is provided. Internal fertilization also explains why true live birth, occurring via the mother's cloaca, is more common in caudates and gymnophionans than in anurans. In such taxa, developing young may obtain nourishment by feeding upon cells and secretions present in the female's reproductive tract.

Patterns of parental care exhibited by anurans include none, maternal only, paternal only and even biparental (to the extent that one species of dart-poison frog appears to form monogamous pairs). Male-only care might be expected to be most likely to evolve if it does not detract from a father's ability to mate with additional females, and so obtain additional fertilizations. This seems to be the case in the European midwife toads, in which males carry fertilized eggs wrapped around their hind limbs on land until embryos are ready to hatch into aquatic larvae (Fig. 1). A male midwife toad can mate with and obtain eggs from as many as two or three females during a single breeding season.

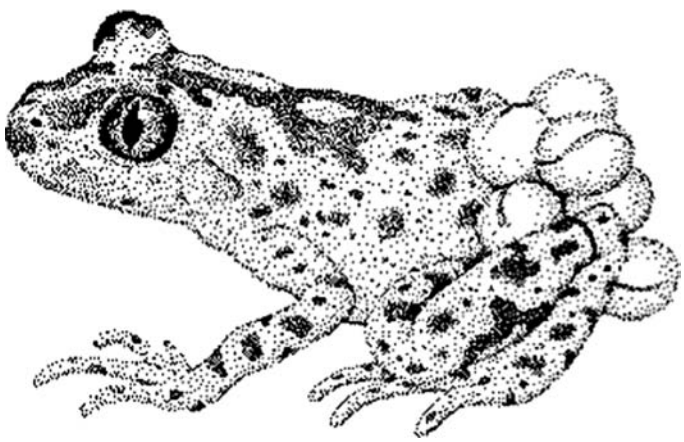

Fig. 1. A male midwife toad carrying fertilized eggs. (Courtesy of Tim Halliday)

Perhaps oddest of all are those anurans in which developing young are protected within specialized parts of the parent's body (retention of embryos within the female's reproductive tract seems to be rare). The diversity here is tremendous; structures involved include pits and pouches of skin on female backs, and throat pouches in males. Most bizarre are the endangered gastric-brooding frogs of Australia. After mating, the female eats her fertilized eggs. Her stomach ceases to produce acid and digestive enzymes, and is transformed into a temporary brooding chamber. In this way, young frogs can be incubated in safety until they are born out of their mother's mouth.

Conclusion

Birds and mammals dominate much of what we know about reproduction in vertebrates, but the diversity in how they reproduce is limited almost to the point of tedium. Thus, all birds and mammals practice internal fertilization. All birds lay eggs, and most mammals give birth to live young. See also and **Reproduction in Mammals: Overview**; and **Reproduction in Reptiles and Birds**.

Reproduction in amphibians is rather different. Superimposed on the basic vertebrate plan of brain–pituitary–gonad, amphibians have evolved extremely diverse modes of reproduction. For example, recall that almost all anurans are external fertilizers, most salamanders are internal fertilizers with indirect sperm transfer, and all gymnophionans are internal fertilizers with direct sperm transfer. At first blush, this level of diversity may seem to defy explanation. But, with further study, amphibians surely will provide us with excellent opportunities to ask how and why both natural and sexual selection favor certain modes of reproduction over others. See also **Amphibia**.

PAUL VERRELL, Washington State University, Pullman, WA

AMPHIBOLE. This is the name given to a closely related group of minerals all showing in common a prismatic cleavage of 54–56° as well as similar optical characteristics and chemical composition.

The amphiboles may be said to represent chemically a series of metasilicates corresponding to the general formula $RSiO_3$ where R may be calcium, magnesium, iron, aluminum, titanium, sodium, or potassium. The crystals of the amphibole family group fall within both the monoclinic and orthorhombic systems.

There is a clear parallelism between the amphiboles and the pyroxenes. There are two basic differences between the minerals of these two family groups; amphiboles with cleavage angles of 56° and 124°, with essential OH groups in their structure; pyroxenes with cleavage angles of 87° and 93°, and being anhydrous, with no OH content. Amphibole crystals are usually long and slender and tend to be simple while pyroxene crystals tend to be complex, short, and stout prisms.

Amphibole is common in both lavas and deep-seated rocks, though less so in the basic lavas than pyroxene. Many of the amphiboles may be developed as metamorphic minerals. The following members of the amphibole group are described under their own headings: actinolite, anthophyllite, cummingtonite, glaucophane, grunerite, hornblende, riebeckite and tremolite. Amphibole was so named by Haüy from the Greek word, meaning doubtful, because of the many varieties of this mineral. See also **Pyroxene**.

AMPHIBOLITE. The amphibolites form a large group of rather important rocks of metamorphic character. As the name implies they are made up very largely of minerals of the amphibole group. There may be also a variety of other minerals present, such as quartz, feldspar, biotite, muscovite, garnet, or chlorite in greater or lesser amounts.

Depending upon the particular amphibole present these rocks may be light to dark green or black, the amphibole usually being in long slender prisms or laths, often quite coarse, sometimes in acicular or fibrous forms.

Because the mineral constituents are arranged parallel to the schistosity, amphibolites may have a strongly developed cleavage.

The occurrence of amphibolites accompanying gneisses, schists, and other metamorphic rocks of probable sedimentary origin strongly suggests a similar derivation. Yet some amphibolites cut other metamorphic rocks in the manner of dikes or sills. It is very likely that they have been derived from both original igneous and sedimentary rocks. Large masses of amphibolite suggest gabbroic stocks. Well-known areas in which amphibolites are found are New England, New York State, Canada, Scotland, and the Alps.

AMPHIDROMIC POINT. A geographic position in the ocean where theoretically there is no tide range and from which cotidal lines radiate in various directions. The tide amplitude presumably increases with distance from this point. A synonym is *nodal point*.

AMPHINEURA. The chitons and allied forms, a group of the phylum *Mollusca*. The more familiar members are flattened marine animals of oval outline. They have a shell composed of a series of separate plates, sometimes concealed within the body. The foot makes up most of the ventral surface and the limited mantle extends down about it to form a shallow groove. Nerve cells are in many cases distributed through the nerve cords so that the nervous system contains no ganglia. See **Ganglion**.

The group has two classes:

Class *Aplacophora (Solenogastres)*. Worm-like animals, somewhat cylindrical and elongate. Shell lacking.

Class *Polyplacophora*. The chitons. Flattened and oval, with shell plates. They are widely distributed, chiefly in the shallow waters. Sometimes used as food.

AMPHIOXUS. Commonly used to designate any of the primitive chordates called lancelets but more accurately a genus of these animals. See **Cephalochordata**.

AMPHIPATHY. The simultaneous attraction and repulsion in a single molecule or ion consisting of one or more groups having an affinity for the phase in which they are dissolved together with groups that tend to be expelled by the medium.

AMPHIPHILIC. Molecule having a water-soluble polar head (hydrophilic) and a water-insoluble organic tail (hydrophobic), e.g., octyl alcohol, sodium stearate. Such molecules are necessary for emulsion formation and for controlling the structure of liquid crystals.

See also **Emulsions**; and **Liquid Crystals**.

AMPHIPODA. An order of crustaceans including marine and freshwater species. The beach-fleas are among the few that have a common name.

AMPHIPROTIC. Capable of acting either as an acid or as a base, i.e., as a proton donor or acceptor, according to the nature of the environment. Thus, aluminum hydroxide dissolves in acids to form salts of aluminum, and it also dissolves in strong bases to form aluminates. Solvents like water, which can act to give protons or accept them, are amphiprotic solvents. See **Acids and Bases**; and **Salt**.

AMPHOLYTE. A substance that can ionize to form either anions or cations and thus may act as either an acid or a base. An ampholytic detergent is cationic in acid media and anionic in base media. Water is an ampholyte.

AMPLIFIER. A device for increasing the strength of a signal without appreciably altering other signal characteristics, such as waveform. Amplifiers may be classified in several ways — by basic mode of operation, such as electronic (solid state or vacuum tube), magnetic, hydraulic, fluidic, and mechanical (level systems); by application, such as data and information systems (computing, electronic data processing, communications, instrumentation) and automatic control systems. In one device or subassembly, other functions may be combined with amplification. The nomenclature of amplifiers reflects these variations in terms of numerous special designations — some by mode of operation as a transistor amplifier, magnetic amplifier, fluidic amplifier, etc.; some by use and specific function as a carrier amplifier, sample-and-hold amplifier, servo-amplifier, power amplifier, etc. Amplifiers also may be classified in terms of their frequency response, or in terms of the signal frequencies they are designed to transmit. This classification is essentially one that depends on the frequency characteristics of the load impedance or coupling network used between transistor amplifier stages. Thus, there are direct current (D.C.) amplifiers, audio frequency amplifiers, rf amplifiers, video frequency amplifiers, etc. Also, recognizing the mechanism of amplification as the control of an output current by an input voltage or current, an amplifier may be classified in terms of the fraction of the cycle of an assumed sinusoidally varying input signal for which the output current flows.

A simple transistor amplifier is shown in Fig. 1. Capacitor C_1 is a blocking capacitor to prevent modification of the bias conditions due to a D.C. path through the generator, R_1 and R_2 in conjunction with the battery and the D.C. voltage developed across R produce the desired bias current in the base lead, and C_2 is a bypass capacitor to eliminate feedback due to signal current flowing through resistor R. The application of an input

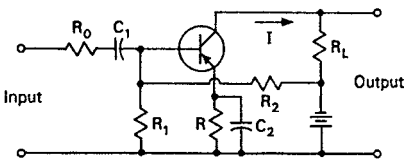

Fig. 1. Common emitter transistor amplifier connection.

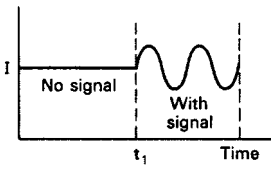

Fig. 2. Waveform in resistance-coupled amplifier.

signal changes the current into the base-emitter junction with a consequent change in collector current I as shown in Fig. 2. The output voltage is developed across resistor R_L as a result of the flow of collector current through it. Resistor R_0 produces a load for the source of signal voltage that is far more constant than the base to emitter resistance of the transistor alone. The input signal current is made much less dependent on the device itself by this means. When the gain obtainable from a single amplifier is not sufficient for a given application, it is necessary to cascade two or more stages. This situation requires coupling networks between amplifier stages that assume a variety of forms depending on the frequency response characteristics desired for the amplifier. A simple and common method is known as resistance coupling. This is coupling in which resistors are used as the input and output impedances of the circuits being coupled. A coupling capacitor can be used between the resistors to transfer the signal from one stage to the next.

Amplifier Configurations. Several specific amplifier configurations are described briefly in the following listing, arranged alphabetically for convenience.

(*Balanced Amplifier*) — An amplifier circuit in which there are two identical signal branches connected so as to operate in phase opposition and with input and output connections each balanced to ground.

(*Booster Amplifier*) — An amplifier used in audio consoles between mixer controls and the master volume control to prevent deterioration of signal-to-noise ratio. It generally supplies sufficient gain to compensate for mixing-circuit losses.

(*Bootstrap Amplifier*) — A single-stage amplifier in which a change in input signal voltage changes the potential of the input source with respect to ground (or other reference voltage) by an amount equal to the output signal voltage. In a transistor amplifier, the input is applied between base and emitter with the output load connected between the emitter and the low potential side of the collector power supply.

(*Bridge Amplifier* — Extensively used for instrumentation purposes, the commercial configuration generally is a direct-coupled amplifier, offering reasonably wide bandwidths up to 50 kHz at gains ranging from near unity to 1,000. See also separate entry on **Bridge Amplifier**.

(*Buffer Amplifier*) — This term is commonly applied to an amplifier stage whose main function is to isolate the oscillation of a transmitter from the main power amplifiers, but it is also applied to any amplifier which is inserted between two circuits or amplifier stages to reduce substantially the interaction of one on the other. The frequency of an oscillator depends, among other factors, upon the load which is applied to it. Since, for satisfactory communications, it is highly desirable that the oscillator frequency remain constant, buffer amplifiers are always used in broadcast transmitters and are usually used in others. Such an amplifier usually operates with the signal current to the input circuit of the buffer amplifier so low that the current taken from the exciting circuit is not sufficient to change its operation appreciably from the no-load condition. The output circuit of the buffer can then supply the normal load of a conventional amplifier without this load affecting the oscillator. Sometimes more than one buffer stage is used to make certain that no load is reflected back to the oscillator. See also **Buffer (Chemical)**.

(*Carrier Amplifier*) — A D.C. amplifier wherein the signal first is modulated, then demodulated during amplification. The bandwidth usually is from zero to some finite frequency. Electronic switches or electromechanical devices are used in most cases to effect the modulation. Thus, the "chopping" action accomplishes the equivalent of a square-wave modulation of the signal. See also separate entry on **Carrier Amplifier**.

(*Cascade Amplifier*) — A series of amplifiers with each output connected to the input of another amplifier (except the last).

(*Chopper Amplifier*) — In one type of chopper amplifier, the input signal is chopped (or modulated), amplified by an A.C. amplifier, demodulated, and filtered to provide a D.C. output signal. See foregoing mentioned description of carrier amplifier. In a second type, the error signal is chopped for the purpose of providing stabilization of gain and offset. The term, chopper-stabilized amplifier, may be a more apt designation. See also separate entry on **Chopper Amplifier**.

(*Common-Base Amplifier*) — A form of transistor amplifier in which the input signal is applied between emitter and base and the output signal is taken between collector and base. See Fig. 3. Characteristics associated with this connection are extremely low input impedance, high output impedance, and a current amplification somewhat less than unity. The circuit is useful in providing impedance transformation from a low impedance source to a high impedance load.

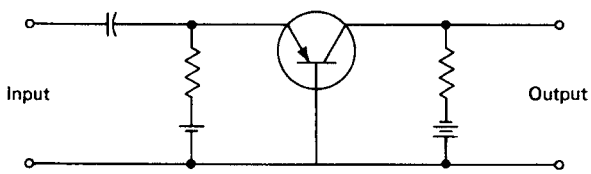

Fig. 3. Common-base transistor amplifier.

(*Common-Emitter Amplifier*) — A form of transistor amplifier in which the input signal is applied between base and emitter and the output signal is taken between collector and emitter. This configuration is capable of providing both current gain and voltage gain exceeding unity in contrast with the characteristics of the common-base and emitter-follower amplifiers. See Fig. 4.

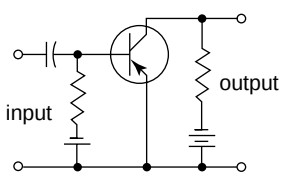

Fig. 4. Common-emitter amplifier.

(*Contact-Modulated Amplifier*) — Used for the amplification of D.C. and very low frequency signals. The signal source is modulated by a carrier-operated contact system (usually 60 to 400 Hz), the resulting modulated wave amplified in an A.C. amplifier to a suitable level, and subsequently demodulated, sometimes by the same contact system used to accomplish the original modulation.

(*Direct-Coupled Amplifier*) — An amplifier in which no coupling capacitors are employed as interstage coupling elements and which thus is capable of amplifying D.C. variations and A.C. signals of arbitrarily low frequency. A transistor direct-coupled amplifier using feedback is shown in Fig. 5. The need for batteries or Zener diodes as coupling elements has been avoided in this design by suitable choice of transistor operating points, values of collector and emitter resistors, and the feedback connections.

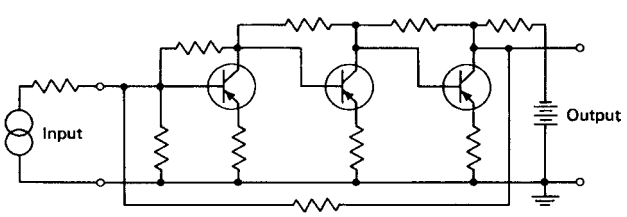

Fig. 5. Direct-coupled transistor amplifier.

(*Distributed Amplifier*) — An amplifier consisting of components appropriately distributed along artificial transmission lines. This amplifier is capable of much greater bandwidths than a conventional amplifier, and the ordinary figure of merit or gain-bandwidth product does not apply.

(*Doherty Amplifier*) — A particular arrangement of a radio-frequency linear power amplifier wherein the amplifier is divided into two sections whose inputs and outputs are connected by quarter-wave (90°) networks, and whose operating parameters are so adjusted that, for all values of the input signal voltage up to one-half maximum amplitude, Section No. 2 is inoperative and Section No. 1 delivers all the power to the load, which presents an impedance at the output of Section No. 1 that is twice the optimum for maximum output. At one-half maximum input level, Section No. 1 is operating at peak efficiency, but is beginning to saturate. Above this level, Section No. 2 comes into operation, thereby decreasing the impedance presented to Section No. 1, which causes it to deliver additional power into the load until, at maximum signal input, both sections are operating at peak efficiency, and each section is delivering one-half the total output power to the load.

(*Double-Stream Amplifier*) — A traveling-wave amplifier in which the amplification occurs as a result of the interaction of two electron beams having different average velocities. The amplification takes place in the beam itself and is a result of what might be called electromechanical interaction.

(*Feedback Amplifier*) — An amplifier in which feedback has been deliberately introduced to obtain certain performance characteristics. Commonly, the feedback connection is made from the output to the input of the amplifier and is employed to reduce variations in gain associated with changes in the characteristics of transistors. A representative feedback amplifier is shown in Fig. 6. In this case, the amplifier acts to maintain the output voltage constant for a constant peak amplitude input signal. The amplifier contains stabilizing networks (N_1) to prevent oscillation.

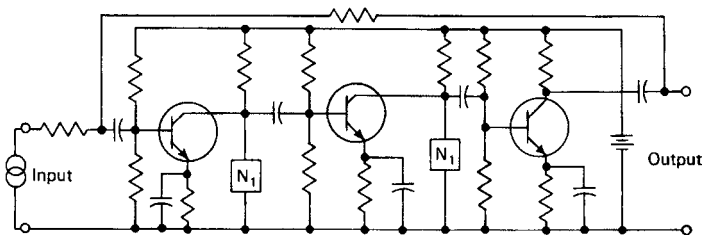

Fig. 6. Transistor feedback amplifier.

(*Floating Amplifier*) — Also known as an isolated amplifier, the design does not require that the input and output signals be referred to the same signal reference point (ground). Generally, differential-input amplifiers meet this definition. The term *floating*, however, normally excludes an amplifier where the input reference point and the output reference point are common, that is, either through a signal conductor or a power supply. Specifically, floating amplifier refers to an amplifier that includes a 4-terminal coupling device, such as a light-coupled signal-transmission element or a transformer. See also separate entry on **Floating Amplifier**.

(*Fluidic Amplifier*) — A fluid amplifier amplifies pressure, mass flow, and fluid power and, in principle, bears considerable resemblance to its electrical/electronic counterparts. Several types of fluidic amplifiers have been designed. See also separate entry on **Fluidics**.

(*Hydraulic Amplifier*) — A power amplifier employed in some servomechanisms and control systems in which power amplification is obtained by the control of the flow of a high-pressure liquid by a valve mechanism. See also separate entry on **Hydraulic Controller**.

(*Impedance-Coupled Amplifier*) — An amplifier similar in form to a resistance-coupled amplifier in which the output voltage drop is developed across a choke or impedance coil. The choke or impedance coil can be designed to have a suitably high impedance at the frequency of the signal being applied and still have a resistance low enough so that only a relatively small voltage drop appears across it at D.C. This form of coupling is usually used in amplifier design to amplify audio-frequency signals.

(*Intermediate-Frequency Amplifier*) — The amplifier used in superheterodyne receivers which amplifies the sum or difference frequency produced in the mixer or first detector by the heterodyning of the signal and oscillator frequencies.

(*Isolated Amplifier*) — See prior item in this list — Floating Amplifier.

(*Klystron Amplifier*) — A klystron tube may be used as an amplifier as well as oscillator in UHF applications. A cascade-amplifier klystron contains three resonant cavities for increased power amplification and output. The third resonator lies between the input and output resonators and has no external connection. It is excited by the bunched beam that emerges from the input-resonator gap, and it produces further bunching of the beam. See also **Microwave Tubes**.

(*Light Amplifier*) — The term laser stands for light amplification by stimulated emission of radiation. A laser is an active electron device that converts input power into a very narrow, intense beam of coherent light. See also separate entry on **Laser**.

(*Linear Amplifier*) — A pulse amplifier in which the output pulse height is proportional to an input pulse height for a given pulse shape up to a point at which the amplifier overloads.

(*Linear Power Amplifier*) — A power amplifier in which the signal output voltage is directly proportional to the signal input voltage.

(*Logarithmic Amplifier*) — An amplifier whose output signal is a logarithmic function of the input signal.

(*Magnetic Amplifier*) — A device that uses saturable reactors either alone or in combination with other circuit elements to achieve amplification. A simple form of magnetic amplifier is shown in Fig. 7. An alternating voltage source is connected in series with a load resistor R_L and two coils (called gate windings) having the same number of turns (N_g). The gate windings are wound on separate cores. A third winding (N_c turns), called a control winding, is wound around the two cores containing the gate windings. The magnetic amplifier functions as an amplifier in that a signal applied to the control winding controls the flow of current in R_L produced by the source of alternating voltage. The control is effected through the action of the gate windings which act as switches which are closed for a fraction of the alternating current cycle which depends on the amplitude of the signal applied to the control winding.

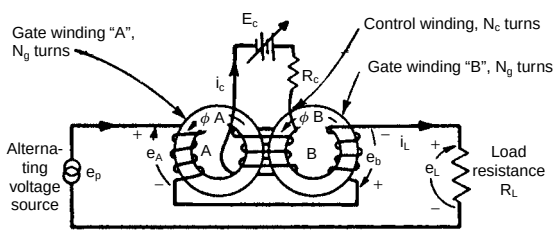

Fig. 7. Elementary magnetic amplifier.

The gate windings act as switches by virtue of the fact that their impedance is very high at one part of the cycle and very low at another part. The behavior of the impedance results from the characteristics of the magnetic material used for the cores on which the gate windings are located. The relation between the magnetomotive force produced by a coil wound on the core and the resulting magnetic flux in the core may be approximated by the graph shown in Fig. 8. Between $-M$ and $+M$ the flux curve has a very steep slope and outside of this range the graph is essentially a horizontal line. In the latter range the magnetic material is said to have reached saturation with a magnetic flux ϕ_s. The potential difference across an inductor is directly proportional to the rate of change of the magnetic flux intercepted by the coil. Conversely, the flux intercepted may be expressed as the time integral of the potential difference. If a sinusoidal voltage is impressed across the terminals of an inductor, the value of flux that results at all instants of time may be determined from the time integral of the sinusoidal voltage.

By knowing the form of the flux-magnetomotive force (ampere-turns) relation (Fig. 8, for example) and the number of turns in the coil, the current that flows through the coil to provide the necessary ampere turns can be determined. Examination of Fig. 8 shows that, for applied voltages such that the flux produced is less than ϕ_s, a comparatively small magnetomotive force is required and hence a relatively small current will result in the coil. The inductor has a very high impedance under this condition. If the applied voltage results in a flux greater than ϕ_s, a large value of magnetomotive force, and thus a large value of current, will be required to satisfy the flux condition. The impedance of the coil for voltage amplitudes above a certain amount will thus be very low. These

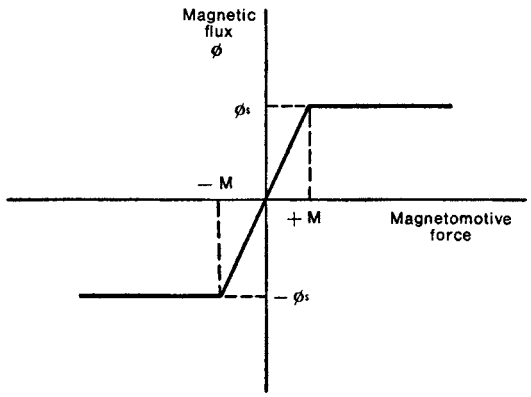

Fig. 8. Approximate relation between flux and magnetomotive force.

notions can also be expressed in terms of the equivalent inductance of the coil which is proportional to the slope of the flux-magnetomotive force curve.

From Fig. 8 it is seen that, for applied voltages resulting in operation between $-M$ and $+M$, the inductance will be very large, whereas outside of this region the inductance will be essentially zero. If a sinusoidal voltage is applied to a coil wound upon a core having the properties shown in Fig. 8, then essentially no current will flow in the coil until the amplitude of the sine wave reaches a critical value (the value corresponding to a flux ϕ_s), but for the time that the amplitude exceeds the critical value, the voltage drop across the coil will be close to zero, and the current that results will be determined principally by the amplitude of the applied voltage and the impedance of any other elements connected in series with the coil.

The ratio of power gain to time constant can be improved if positive feedback is applied to the amplifier of Fig. 7. The circuit with the feedback connection, as well as a bridge rectifier to provide a unidirectional load current, is shown in Fig. 9. For simplicity the control winding is shown as two separate windings, one on each core. In the circuit, the load current which, although it pulsates, always flows in one direction, is forced to flow through two feedback windings which are arranged so that their magnetomotive forces reenforce those created by the control windings on both cores. The ampere turns contributed by control plus feedback windings are still approximately equal to those contributed by the gate windings, but because of the contribution of the feedback winding the control winding ampere turns for a given load current can be much less than without the feedback.

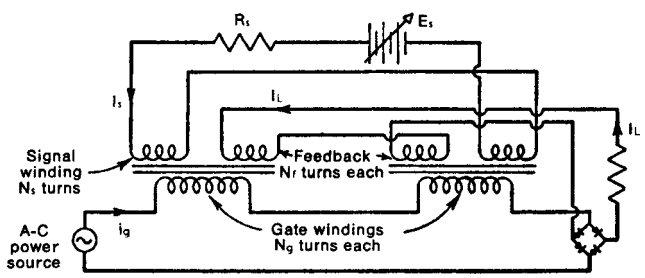

Fig. 9. Magnetic amplifier with external feedback.

Two representative magnetic amplifier circuits are shown in Figs. 10 and 11.

(*Magnetron Amplifier*) — A traveling-wave magnetron used as an amplifier. The basic features of a typical structure are shown in Fig. 12. It resembles a section of a vane-type, cavity magnetron of infinite radius, excited at one end, and coupled to a load at the opposite end. A beam of electrons is projected through the space between the plane electrode and the cavity structure, which is maintained at a positive potential relative to the plane electrode. A magnetic field, normal to the plane of the paper, is adjusted so that the electrons do not strike the anode in the absence of alternating field. If the velocity of the electron beam is equal to, or nearly equal to, the phase velocity with which electromagnetic waves move down

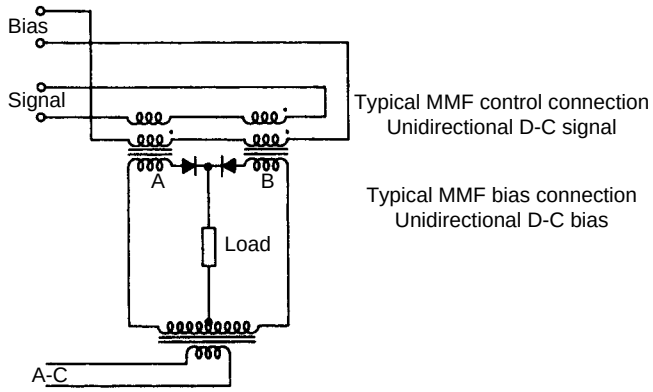

Fig. 10. Self-saturating magnetic amplifier circuit.

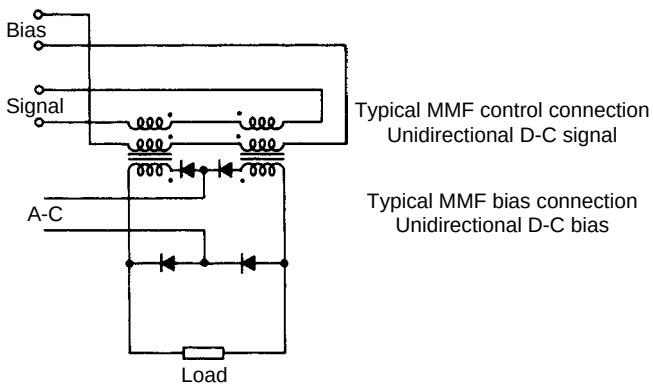

Fig. 11. Magnetic amplifier doubler circuit.

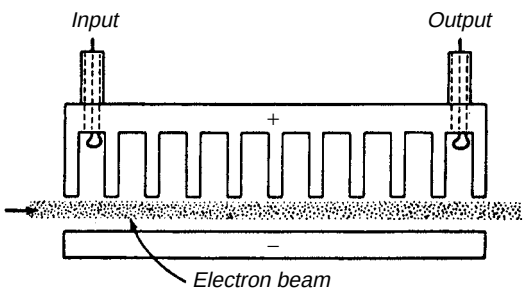

Fig. 12. Magnetron amplifier structure. Magnetic field is perpendicular to plane of paper.

the loaded waveguide formed by the cathode and anode, energy is transferred to the electromagnetic wave from the source of direct voltage. The electromagnetic wave that moves from the input resonator to the output resonator, therefore, increases in amplitude, and the power output exceeds the power input.

(*Microwave Amplifier*) — The term maser stands for microwave amplification by stimulated emission of radiation. The amplification in a microwave amplifier is achieved by raising atoms or molecules of a paramagnetic material to an unstable high energy level. See also separate entry on **Maser**.

(*Modulated Amplifier*) — An amplifier stage in a transmitter in which the modulating signal is introduced and modulates the carrier.

(*Monitoring Amplifier*) — In broadcasting and recording, an amplifier with high input impedance and medium power output which is bridged across the program circuit. The available power output is used to operate a loudspeaker and/or headsets for the benefit of control personnel.

(*Nonlinear Amplifier*) — An amplifier in which the output is not related to the input by a simple constant. One form is the volume-limiting amplifier, where the average gain is changed in such a manner that steady-state waveforms are accurately reproduced; another form, frequently called

a clipping or over-driven amplifier, has an output which is a greatly distorted version of the input.

(*Operational Amplifier*) — Used to perform analog-computer functions, an operational amplifier is an amplifier with high D.C. stability and high immunity to oscillation, usually achieved by using a large amount of negative feedback. The operational-amplifier integrator shown in Fig. 13 is used in the conversion of voltage to a frequency. This is an amplifier with a capacitor connected between output and input and is used in digital voltmeters. As shown, there is a resistor in front of the input to the integrator. The amplifier is assumed to have a high gain. As the result of this configuration, the application of a step input results in a linear ramp output in which the slope of the ramp is proportional to the input-voltage step. The basic circuit of another integrating device making use of an operational amplifier is shown in Fig. 14. The voltage appearing at the output of the amplifier is proportional to the integral of the input voltage e_i, or $e_0 = 1/RC \int_{t0}^{ti} e_i dt$.

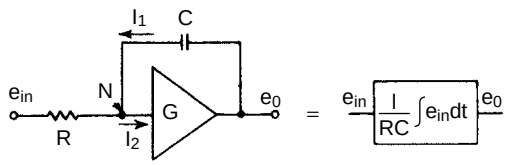

Fig. 13. Operational-amplifier integrator.

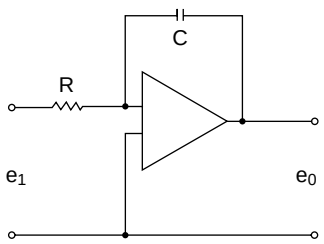

Fig. 14. Operational amplifier with capacitance feedback.

(*Paramagnetic Amplifier*) — An amplifier which increases the power level of a signal by means of the variations of an energy-storage parameter.

The classic example is the L-C resonant circuit in which the spacing of the capacitor plates is varied cyclically by a "pump" at a frequency ω_p, twice the signal frequency ω_s, which is identical to the resonant frequency of the circuit. Initial charge on the capacitor will result in a sinusoidal variation of capacitance charge as a function of time. If the capacitance is always decreased by the pump at the plus or minus peak of charge during which time charge is relatively constant, an increase in capacitor voltage must result, since $C = QV$. This increase in capacitor voltage represents an increase in the power level of the original signal, the additional energy representing the work done by the pump in increasing the separation of the capacitor plates against the forces of electrostatic attraction.

Maximum energy will be transferred from the pump frequency to the signal frequency if the pump frequency is twice the signal frequency and if the relative phase of the two is adjusted as described above. In a practical case, the separation of the two frequencies cannot be conveniently maintained constant. Therefore, the signal and pump will no longer interact favorably all the time, but will drift periodically into and out of the optimum condition. This produces a modulation of the signal frequency, resulting in frequency components in the output, among which are ω_s, ω_p, and $(\omega_p - \omega_s)$ the latter term being called the *image* or *idler* signal.

The mode of operation described above is called a *negative resistance amplifier*, since it acts to neutralize or overcome the positive resistance of the resonant circuit. Stability problems arise, since the output and input terminals are inherently the same. The closeness of the image frequency to the signal frequency makes the separation of the two difficult, one procedure being the utilization of a circulator. The pump signal can be filtered from the output by a conventional band-elimination filter.

A slightly different mode of operation, called variously the *up-conversion amplifier* or *amplifying-up converter*, differs from the negative resistance type of amplifier in these respects: (1) Since the gain can be shown to be proportional to $\omega_s + \omega_p/\omega_s$, the pump frequency is made as high as is practicable. (2) An additional frequency of interest is $(\omega_s + \omega_p)$. The signal frequency is inevitably shifted in the amplification process. (3) The up-converter is a two-part device with unconditional stability, without the requirement of a circulator.

A reverse-biased semiconductor diode provides an excellent nonlinear reactive element for use in a parametric amplifier inasmuch as it presents a very high shunt resistance and a capacitance that varies approximately inversely with the square root of the applied voltage. Thus, it is common practice to employ these elements as the capacitor C in Fig. 15. Parametric amplification can also be achieved by the utilization of the nonlinear characteristics of ferromagnetic and ferroelectric materials.

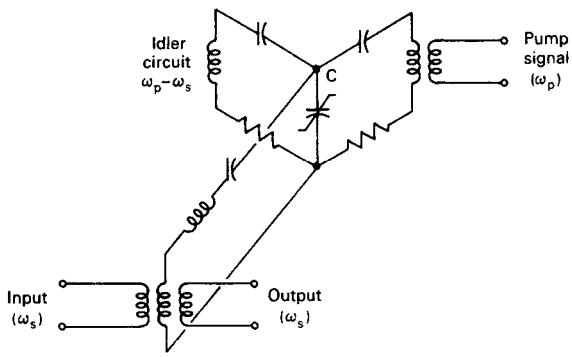

Fig. 15. Parametric amplifier.

(*Paraphase Amplifier*) — A phase-inverter amplifier used to convert a single-ended signal to a push-pull signal.

(*Pentriode Amplifier*) — A video amplifier containing a pentode which by virtue of suitable bypass and coupling devices, is made to operate as a triode (screen effectively connected to the plate) over a portion of the frequency range, and as a pentode (screen-grounded) over another part of the frequency range.

(*Pneumatic Amplifier*) — A device that increases signal strength pneumatically — as say a 3–15 psi (155–776 torr) instrument signal to several hundred psi to operate a large piece of process equipment, such as a slide valve, damper, furnace door, etc. Usually, such terms as booster, positioner, and relay, are used instead of amplifier.

(*Power Amplifier*) — An amplifier adjusted to operate with the objective of developing power in the load impedance in contrast with emphasis on production of output voltage or current. In many applications it is necessary to get power from an amplifier unit, so at least the final stage is usually adjusted to give power rather than voltage output. In radio-transmitting circuits or large power audio-amplifiers several stages may be power amplifiers. For this type of service the circuit is adjusted to give as large a current as possible through the load, which has much lower resistance than in voltage amplifiers. The transistors used are somewhat larger as a rule than those used for voltage and current amplification and are specially designed for large current outputs.

(*Preamplifier*) — This is a voltage amplifier, which receives the signal from a microphone, pick-up, television camera tube, or other device supplying a low signal level and amplifies it so it can supply the input for additional amplifier circuits. Thus a preamplifier is commonly used in a radio or television studio to amplify the audio or video signal before feeding it into a mixer, line to the transmitter, or other amplifying equipment at the studio.

(*Program Amplifier*) — The amplifier following the master volume control in an audio console. Its gain brings the signal to a level suitable for transmission.

(*Push-Pull Amplifier*) — An amplifier in which the input signals applied to the transistors are opposite in phase and the output signals are combined to obtain twice the output of a single stage. Push-pull amplifiers have lower harmonic distortion than amplifiers with one transistor and with transformer-coupling they have the added advantage that the collector currents for the two devices act to magnetize the transformer core in opposite directions, tending to avoid saturation of the core. If the devices are perfectly balanced, no signal voltage exists across the bias resistor and a bypass capacitor normally used can be omitted.

The property of complementary symmetry makes it possible to dispense with a phase inverter in some push-pull transistor amplifiers. Figure 16 shows a push-pull amplifier formed from two common-collector connected transistors. Since the circuit has a low output impedance, it may be used for direct coupling to a loudspeaker without a transformer. This arrangement employs one *n-p-n* and one *p-n-p* transistor. Because of the complementary symmetry property, a positive signal current injected into the base of the *n-p-n* unit will cause its collector current to increase, whereas the same positive injected signal will cause the collector current of the *p-n-p* unit to decrease. As a result, the two base connections may be supplied from one signal source. In the figure the resistors connecting collectors and bases provide a small forward bias on the transistors. The resistance *R* is sufficiently low so that both transistors have essentially equal input currents.

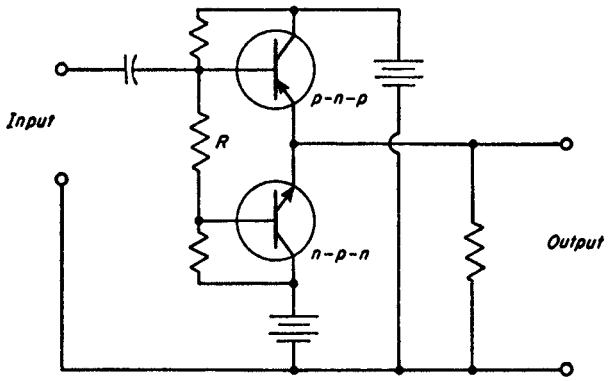

Fig. 16. Complementary symmetry push-pull amplifier.

(*Reflex Circuit Amplifier*) — A circuit in which a transistor simultaneously amplifies signals in two widely- separate frequency bands (i.e., the intermediate frequency signal of a superheterodyne and the audio-frequency output of the detector). Used very rarely because the savings of material and space are not justified by the additional complexity of operation.

(*Sample-and-Hold Amplifier*) — Also known as a track-and-hold amplifier, this device has an output that is proportional to the input until a "hold" signal is received. Upon receipt of that signal, the amplifier output is maintained essentially constant even though there may be changes in the input signal. See also separate entry on **Sample-and-Hold Amplifier**.

(*Servo-amplifier*) — An amplifier used in a control or servo-system.

(*Single-Ended Amplifier*) — An amplifier in which each stage normally employs only one transistor, or if more than one such device is used, in which they are connected in parallel so that operation is asymmetric with respect to ground. See also separate entry on **Single-Ended Amplifier**.

(*Single-Ended Push-Pull Amplifier*) — A form of amplifier in which a pair of output terminals may have an instantaneous voltage of either polarity as may be dictated by the phase of the input signal.

(*Stagger-Tuned Amplifier*) — An amplifier incorporating staggered tuning to provide a desired bandwidth characteristic.

(*Step-Down Amplifier*) — A vacuum-tube type amplifier used to measure very high potentials which are impressed between anode and cathode, the anode being negative. The corresponding grid current is measured with the grid positive. This is sometimes called an "inverted voltmeter."

(*Transformer-Coupled Amplifier*) — An amplifier in which the interstage coupling from the output of one amplifying stage to the input of the next or to the load impedance is made using a transformer. The coupling method is used in audio-frequency amplifiers. The method is particularly advantageous in the opportunity offered for impedance matching when the load is a speaker or a low impedance transmission line. In Fig. 17 is shown the audio output stage of a transistor radio receiver. Changes in the base current resulting from the input signal cause corresponding changes in collector current which flows through the primary winding of the transformer. There results an alternating voltage across the secondary which has the same form as the input signal to the base and is capable of providing the necessary power output from the speaker. In this instance, the transformer makes possible matching the relatively low impedance of the speaker to the much higher output impedance of the transistor.

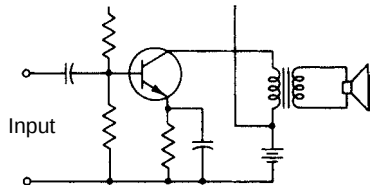

Fig. 17. Transistor audio amplifier.

(*Traveling-Wave Amplifier*) — An amplifier that uses one or more traveling-wave tubes to provide amplification of signals at frequencies of the order of thousands of megacycles.

(*Tuned Amplifier*) — An amplifier in which the load impedance consists of, generally, a parallel inductance-capacitance network, or two or more of these having electromagnetic coupling. The fact that the impedance of this network varies with frequency causes the gain of the amplifier to vary as a function of frequency in a somewhat similar manner. A tuned amplifier, employing a transistor and used for the amplification of intermediate frequency signals, is shown in Fig. 18. A tuned primary circuit is used and the transistor is connected across only a portion of the inductor. The arrangement offers advantages from the standpoint of impedance matching that permit higher gains to be achieved than would be possible otherwise in view of typical transistor characteristics.

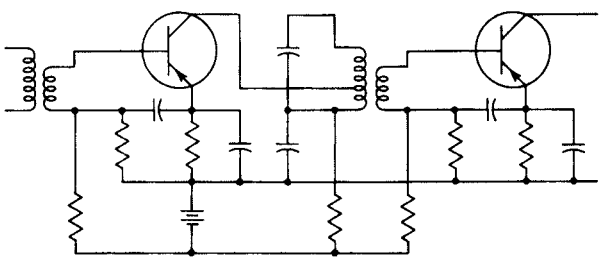

Fig. 18. Transistor intermediate-frequency amplifier.

(*Video-Frequency Amplifier*) — A device capable of amplifying such signals of wide bandwidth as are used in television and radar.

(*Voltage Amplifier*) — An amplifier designed for the primary purpose of producing an increase in signal voltage with little or no attention to the available output power of the stage.

(*Volume-Limiting Amplifier*) — An amplifier containing an automatic device which functions when the input volume exceeds a predetermined level, and so reduces the gain that the output volume is thereafter maintained substantially constant, notwithstanding further increase in the input volume. The normal gain of the amplifier is restored when the input volume returns below the predetermined limiting level.

(*Wide-Band Amplifier*) — An amplifier having uniform response over many decades of frequency. An example is the video amplifier.

AMPLITUDE. 1. The maximum value of the displacement of a wave or other periodic phenomenon from a reference position.

2. Angular distance north or south of the prime vertical; the arc of the horizon, or the angle at the zenith between the prime vertical and a vertical circle, measured north or south from the prime vertical to the vertical circle.

The term is customarily used only with reference to bodies whose centers are on the celestial horizon, and is prefixed E or W, as the body is rising or setting, respectively; and suffixed N or S to agree with the declination. The prefix indicates the origin, and the suffix indicates the direction of measurement. Amplitude is designated as true, magnetic, compass, or grid as the reference direction is true, magnetic, compass, or grid east or west, respectively.

AMPLITUDE COMPARISON. The process of indicating the time at which two waveforms reach the same amplitude. It may also be considered to be the method of determining the abscissa of a waveform, given its ordinate.

AMPLITUDE DISCRIMINATOR. A circuit that performs an amplitude comparison. In addition, the sense and magnitude of the inequality of the amplitudes may be obtained.

AMPLITUDE-MODULATED INDICATOR. One of two general classes of radar indicator in which the sweep of the electron beam is deflected vertically or horizontally from a base line to indicate the existence of an echo from a target. Also called *deflection-modulated indicator*.

The amount of deflection is usually a function of the echo signal strength. Common types of amplitude-modulated indicators give only the slant range between radar and target. However, since the characteristics of the target signal can be easily observed with this type of indicator, it is very useful in radar meteorology.

AMPLITUDE MODULATION. Changing the amplitude of a carrier wave by some means so that the resultant waveform transmits a signal conveying information.

For example, if the carrier wave with angular frequency ω is $\cos(\omega t)$, the corresponding amplitude-modulated signal is

$$f(t) = g(t)\cos(\omega t),$$

where $g(t)$ is a function that varies more slowly with time than does the carrier wave. See also **Modulation**.

AMPLITUDE SEPARATION. The process of separating all values of a wave greater or less than a given amplitude, or those lying between two amplitudes.

AMPLITUDE SPECTRUM. In the Fourier or spectral analysis of two time series, a measure of the correlation between the two series as a function of frequency or wavelength, but ignoring any phase differences between the two time series.

It is defined as

$$Am(n) = Q^2(n) + Co^2(n),$$

where n is wavenumber (number of waves per total period of the time series), $Co(n)$ is the cospectrum, and $Q(n)$ is the quadrature spectrum.

AMS

AMPOULE. Sometimes spelled ampule, a small sealed glass container for drugs that are to be given by injection. As they are completely sealed, the contents are kept in their original sterile condition.

AMPULLA. Any flask-like dilatation, such as the small saccular outgrowth of the water vascular system of starfishes, at the inner end of the tube foot, or the dilated portion of the semicircular canals of the vertebrate ear.

AMSLER GRID. The Amsler Grid is a simple eye test used for detecting defects or distortion in the central or "straight ahead" field of vision such as that used for reading or looking at a face. The grid consists of horizontal and vertical black lines on a white background, or sometimes white lines on a black background.

The Amsler Grid was originally developed by Marc Amsler to allow patients to test their own central vision for early signs of macular degeneration, a disease that affects the small central portion of the retina called the macula. Although the macula is only about $\frac{1}{4}$ inch in diameter, it controls virtually all of the eye's central vision. Macular degeneration occurs most often after the age of 50 and is the most common cause of irreversible loss of central vision in the United States. Early detection of the problem is critical to saving eyesight.

The Amsler Grid is also used to detect macular edema, a common cause of severe visual impairment brought on by diabetes. See also **Macula**.

Vision Rx., Elmsford, NY

AMYGDALOID. A vesicular rock, commonly lava, whose cavities have become filled with a secondary deposit of mineral material such as quartz, calcite, and zeolites. The term is derived from the Greek word meaning almond in reference to the frequent almondlike appearance of the filled vesicles, which are called amygdales or amygdules.

AMYL. The 5-carbon aliphatic group C_5H_{11}, also known as pentyl. Eight isometric arrangements (exclusive of optical isomers) are possible. The amyl compounds occur (as in fusel oil) or are formed (as from the petroleum pentanes) as mixtures of several isomers, and, since their boiling points are close and their other properties similar, it is neither easy nor usually necessary to purify them.

See also **Amyl Alcohols**.

AMYL ALCOHOLS. Amyl alcohol describes any saturated aliphatic alcohol containing five carbon atoms. This class consists of three pentanols, four substituted butanols, and a disubstituted propanol, i.e., eight structural isomers $C_5H_{12}O$: four primary, three secondary, and one tertiary alcohol. In addition, 2-pentanol, 2-methyl-1-butanol, and 3-methyl-2-butanol have chiral centers and hence two enantiomeric forms.

The odd-carbon structure and the extent of branching provide amyl alcohols with unique physical and solubility properties and often offer ideal properties for solvent, surfactant, extraction, gasoline additive, and fragrance applications. Amyl alcohols have been produced by various commercial processes in past years. Today the most important industrial process is low pressure rhodium-catalyzed hydroformylation (oxo process) of butenes. See also **Oxo Process**.

Mixtures of isomeric amyl alcohols (1-pentanol and 2-methyl-1-butanol) are often preferred because they are less expensive to produce commercially; also, the different degree of branching of the mixture imparts a more desirable combination of properties.

With the exception of neopentyl alcohol (mp 53 °C), the amyl alcohols are clear, colorless liquids under atmospheric conditions, with characteristic, slightly pungent and penetrating odors. They have relatively higher boiling points than ketonic or hydrocarbon counterparts and are considered intermediate boiling solvents for coating systems (Table 1).

Commercial primary amyl alcohol is a mixture of 1-pentanol and 2-methyl-1-butanol, in a ratio of ca 65 to 35.

Like the lower alcohols, amyl alcohols are completely miscible with numerous organic solvents and are excellent solvents for nitrocellulose, resin lacquers, higher esters, and various natural and synthetic gums and resins. However, in contrast to the lower alcohols, they are only slightly soluble in water. Only 2-methyl-2-butanol exhibits significant water solubility.

The amyl alcohols undergo the typical reactions of alcohols that are characterized by cleavage at either the oxygen — hydrogen or carbon — oxygen bonds. Important reactions include dehydration, esterification, oxidation, amination, etherification, and condensation.

Three significant commercial processes for the production of amyl alcohols include separation from fusel oils, chlorination of C-5 alkanes with subsequent hydrolysis to produce a mixture of seven of the

eight isomers (Pennsalt), and a low pressure oxo process, or hydroformylation, of C-4 olefins followed by hydrogenation of the resultant C-5 aldehydes.

The oxo process is the principal one in practice today; only minor quantities, mainly in Europe, are obtained from separation from fusel oil. *tert*-Amyl alcohol is produced on a commercial scale in lower volume by hydration of amylenes.

The main effects of prolonged exposure to amyl alcohols are irritation to mucous membranes and upper respiratory tract, significant depression of the central nervous system, and narcotic effects from vapor inhalation or oral absorption. All the alcohols are harmful if inhaled or swallowed, appreciably irritating to the eyes and somewhat irritating to uncovered skin on repeated exposure. Prolonged exposure causes nausea, coughing, diarrhea, vertigo, drowsiness, headache, and vomiting. 3-Methyl-1-butanol has demonstrated carcinogenic activity in animal studies.

All of the amyl alcohols are TSCA and EINECS (European Inventory of Existing Commercial Chemical Substances) registered.

The amyl alcohols are readily flammable substances; *tert*-amyl alcohol is the most flammable (closed cup flash point, 19 °C). Their vapors can form explosive mixtures with air.

ANACLINAL. Used in structural geology to define a direction opposite to the dip of the strata or formations.

ANACOUSTIC ZONE. The region above an altitude of about 100 miles where the distance between the air molecules is greater than the wavelength of sound, and sound waves can no longer be propagated.

ANAEROBE. An organism that can grow in the absence of free oxygen and referred to as an anaerobic organism. Subdivided into *facultative anaerobes*, which can grow and utilize oxygen when it is present; and obligatory anaerobes, which cannot tolerate even a trace of oxygen in their surroundings. Yeast is an example of a facultative anaerobe. Yeast can grow and utilize oxygen in its metabolism, in which case it utilizes all the energy in a carbohydrate and yields water and carbon dioxide. In the absence of oxygen, the yeast cells turn to fermentation and anaerobic metabolism wherein the carbohydrate is converted into alcohol and carbon dioxide. The bacterium which produces botulism in "preserved" foods is an obligatory anaerobe (*Clostridium botulinum*).

In addition to botulism, other species of Clostridium are the etiological agents of tetanus, gas gangrene, and a variety of animal diseases including struck, lamb dysentery, pulpy kidney, and enterotoxemia. The pathogenesis of the clostridia depends largely on the production of potent toxins. Generally, these are heat labile exotoxins and often several pharmacologically and immunologically different toxins may be produced by the same species. In recent years, certain of the toxins have been purified to the point of crystalline purity and revealed to be high-molecular-weight proteins. The availability of the pure toxins has permitted more precise studies both of the chemical nature of the toxin and also of their properties as enzymes. From such toxins, it is possible to produce efficient toxoids for use in prophylactic immunization measures for tetanus and botulism. Some clostridia, in contrast, are beneficial. In addition to the nitrogen-fixing ability of certain species, *C. sporogenes* is active in the decomposition of proteins and contributes to biodegradability of substances, particularly of plant remains. *C. acetobutyleium* is active in production of acetone and butyl alcohol by fermentation.

Glucose can be broken down through glycolysis into pyruvic acid, but in the absence of oxygen as a final acceptor for the hydrogen, the pyruvic acid cannot enter the tricarboxylic acid cycle for further breakdown.

Instead the pyruvic acid itself serves as an acceptor for the hydrogen split off in glycolysis. Hence, much less energy is obtained from food in anaerobic metabolism. Lactic acid, alcohol, and some extremely poisonous substances are products of anaerobic metabolism.

In addition to the one-celled anaerobes, certain parasitic worms, such as *Ascaris*, are thought to use anaerobic metabolism, to a certain extent at least. Living in the intestine of higher animals these worms have little access to free oxygen.

The muscles of higher animals are also known to use anaerobic metabolism when the demands on the muscles for energy are greater than can be supplied through the available oxygen. Lactic acid is generated.

The diverse mechanisms that permit animal life in the absence of oxygen are described in considerable detail by P.W. Hochachka ("Living without Oxygen," Harvard Univ. Press, Cambridge, Massachusetts, 1980).

ANALCIME. A common zeolite mineral, $NaAlSi_2O_6 \cdot H_2O$, a hydrous soda-aluminum silicate. It crystallizes in the isometric system, hardness, 5–5.5; specific gravity, 2.2; vitreous luster; colorless to white; but may be grayish, greenish, yellowish, or reddish. Its trapezohedral crystal resembles garnet but is softer; it is distinguished from leucite only by chemical tests.

There are many excellent European localities. Magnificent crystals occur at Mt. St. Hilaire, Quebec, Canada; in the United States at Bergen Hill and West Paterson, New Jersey, Keweenaw County, Michigan, and Jefferson County, Colorado. Nova Scotia furnishes beautiful specimens.

Analcime is a relatively common mineral and occurs with other zeolites in cavities and fissures in basic igneous rocks, occasionally in granites or gneisses. It seems to occur as a replacement and perhaps in some cases as a primary mineral crystallizing from a magma rich in soda and water vapor under pressure. The name analcime is derived from the Greek word meaning weak, in reference to the weak electric charge developed when heated or subjected to friction.

ANAL FEELERS. Posterior sensory appendages, such as the anal cirri of annelid worms and the cerri of insects.

ANALGESICS, ANTIPYRETICS, AND ANTIINFLAMMATORY AGENTS. Pain, pyresis, and inflammation are distinct physiological responses which can occur independently; they are often associated as the body mounts a response to an injury or insult. Each is an important signal from injured tissue and the signal's continued presence can guide a physician in diagnosing and treating the condition which led to the occurrence.

It is increasingly apparent that the central and peripheral nervous systems are capable of causing the production of mediators which can attract and activate inflammatory cells, thereby initiating or amplifying an inflammatory response. At the same time, inflammatory cells are also capable of releasing substances which not only respond to the original insult, but also stimulate the nervous systems.

A number of interdependent physiological mechanisms, each providing new targets for therapeutic intervention, and allowing for the development of new treatments for pain, pyresis, and inflammation, have been discovered. At least eight distinct types of opioid receptors have been identified and the corresponding individual functions are beginning to be understood. Moreover, a great deal has been learned about the role of lipid mediators in the inflammatory response and how antiinflammatory agents control their production.

In 1973 evidence was provided for the existence of receptors which recognize opioid molecules [Pert and Snyder]. As many as eight opioid receptors are known to exist, but only four, designated as μ (mu), κ (kappa), ς (sigma), and δ (delta), are believed to be important to the central nervous system (CNS). Several portions of the brain, including the hypothalamus and amygdala, the spinal cord, and nuclei concerned with vagal reflexes contain varying concentrations of the different types of opioid receptors. See also **Central and Peripheral Nervous System**.

The development of selective agonists and antagonists has aided in formulating a profile of pharmacological effects for each receptor type [Galligan, et al]. The best understood is the μ receptor which plays a role in euphoria, respiratory depression, tolerance, and physical dependence as well as analgesic effects. Studies using highly selective agonists and antagonists imply that there may be μ receptor subtypes [Heyman, et al.] suggesting that not all of the ascribed effects result from the same receptor. Antinociceptive activities and possible modulation of selected μ receptor activities can be identified. In addition to analgesia, the κ receptor effects include diuresis, sedation, and physical dependence [Leander]. The effects of the δ receptor are less well understood as there is a lack of highly selective receptor ligands.

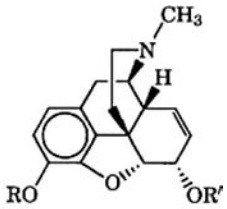
Shortly following the discovery of the opioid receptors, peptidic substances having opioid activity were detected in the pituitary gland [Hughes, et al.]. There are three known groups of endogenous opioid peptides: endorphins [Li, and Chung], enkephalins, and dynorphins. Every member of the three families is the progeny of a distinct polypeptide precursor. The endorphins are fragments of proopiomelanocortin [CAS: 66796-54-1] (POMC), a polypeptide also containing β-lipotropic hormone, adrenocorticotropic hormone (ACTH), and melanocyte stimulatory hormone (α-MSH) [Eipper and Mains]. β-Endorphin, the largest endogenous opioid peptide, is principally synthesized, stored, and ultimately released from cells in the pituitary gland as well as from neurons in the CNS. Although β-endorphin contains the sequence for met-enkephalin, $C_{27}H_{35}N_5O_7S$, the endorphin is not processed to this enkephalin. Instead met-enkephalin is derived from proenkephalin, a polypeptide containing 6 met-enkephalins and 1 leu-enkephalin, $C_{28}H_{37}N_5O_7$ [Lewis et al.]. These highly conserved, five amino acid peptides are located in the adrenal medulla, the CNS, and the peripheral nervous systems. Another polypeptide, prodynorphin also contains a leu-enkephalin fragment, as well as other peptidic opioids, including α - and β-neoendorphin and dynorphin A (1-17), $C_{99}H_{155}N_{31}O_{23}$. The latter is further cleaved to dynorphin A (1-8) and dynorphin B (1-3).

When released, endogenous opioids act upon specific receptors, displaying effects like the quintessential opioid, morphine [CAS: 57-27-2], $C_{17}H_{19}NO_3$. These endogenous peptides appear to induce analgesia and depress respiratory function, gastrointestinal transit, and several other physiological functions. Leu-enkephalin binds with relatively high selectivity to the δ receptor, dynorphin A(1–17) to the κ receptor. Like morphine, β-endorphin, and met-enkephalin are μ agonists. When administered intravenously, β-endorphin was three times more potent than morphine on a molar basis even though the large size and charged nature of β-endorphin should preclude its passage across the blood-brain barrier. See also **Blood-Brain Barrier**. The smaller enkephalins and dynorphins are potential substrates for peptidase degradation when administered systemically. Synthetic enkephalin analogues, designed to resist degradation, demonstrated analgesia in humans. Unfortunately, like morphine, these compounds do not cause analgesia without tolerance and physical dependence.

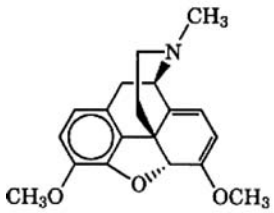
Opioid Agonists

Opium is the dried, powdered sap of the unripe seed pod of *Papaver somniferum*, a poppy plant indigenous to Asia Minor. Theophrastus described its medical properties in the third century BC, but the Sumerians, ca BC 4000, probably perceived its utility. Arab physicians knew of the drug, and Arab traders carried it to the Orient where it was used as a treatment for dysentery. Paracelsus is credited with repopularizing the drug in western Europe in the early sixteenth century by formulating opium into "laudanum", which is still in use. More than 20 different alkaloids of two different classes comprise 25% of the weight of dry opium. The benzylisoquinolines, characterized by papaverine [CAS: 58-74-2] (1.0%), a smooth muscle relaxant, and noscapine [CAS: 128-62-1] (6.0%), an antitussive agent, do not have any analgesic effects. The phenanthrenes, the second group, are the more common and include 10% morphine

(1, R′=R=H), 0.5% codeine [CAS: 76-57-3], $C_{18}H_{21}NO_3$, (1, R′=H, R=CH_3), and 0.2% thebaine [CAS: 115-37-7], $C_{19}H_{21}NO_3$, (2).



(1)



(2)

Morphine, mol wt 285.3, effectively relieves pain and increases an individual's ability to tolerate a painful experience. It also produces a remarkably broad range of other effects, including drowsiness, mood changes, respiratory depression, nausea, decreased gastrointestinal motility, and vomiting. Morphine behaves as a receptor agonist, acting preferentially at the μ receptor, but also exhibiting appreciable affinity for other opioid receptors. A standard therapeutic dose is 10–15 mg, usually administered subcutaneously. Analgesia peaks in about one hour and lasts for four to five hours. An important feature of morphine and related drugs is the development of physical dependence on, and tolerance to, some of the effects.

Codein, mol wt 299.3, is a significantly less potent analgesic than morphine, requiring 60 mg (0.20 mmol) to equal the effectiveness of 10 mg (0.04 mmol) of morphine. However, codeine is orally effective, and it is less addictive and associated with less nausea than morphine.

Introduced in 1898, heroin (1, R=R′=$COCH_3$) was heralded as a nonaddictive alternative to morphine. Subsequent clinical experience showed it to be highly addictive and preferred by addicts over morphine.

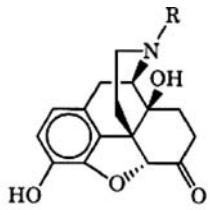
Synthetic and Semisynthetic Agonists

In attempts to discover drugs demonstrating fewer undesirable side effects than morphine, many synthetic analogues have been prepared. Some of these are levorphanol [77-07-6], $C_{17}H_{23}NO$; hydromorphone [466-99-9], $C_{17}H_{19}NO_3$; oxymorphone [76-41-5], $C_{17}H_{19}NO_4$; phenazocine [127-35-5], $C_{22}H_{27}NO$; fentanyl [437-38-7], $C_{22}H_{29}NO_2$.

Several common structural features necessary for opioid, analgesic activity have been identified from the action of the analogues. Systematic simplification demonstrated that much of the morphine ring structure could be modified or even eliminated. The piperidine ring, in a chair conformation, and in particular the nitrogen atom of that ring, appears essential to pharmacological activity. The nitrogen is believed to attach to an anionic center in the receptor. Also crucial is the presence of the phenyl ring which, through van der Waals forces, binds to the hydrophobic portion of the receptor. See also **Van Der Waals Forces**.

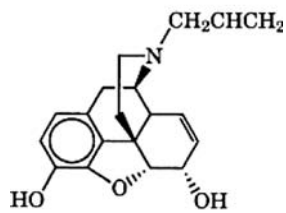
Opioid Antagonists and Partial Agonists

The replacement of the *N*-methyl group on the nitrogen atom of the piperidine ring of morphine and analogues, by allyl, isopropyl, or methyl cyclopropyl, an isopropyl isostere, results in compounds which antagonize opioid responses, especially respiratory depression. Naloxone [CAS: 465-65-6] (3), $C_{19}H_{21}NO_4$, and naltrexone [CAS: 16590-41-3] (4), $C_{20}H_{23}NO_4$, are both derived from oxymorphone and exhibit agonist activity only at doses that are of little clinical significance. In the absence of opioid drugs, naloxone does not cause analgesia, respiratory depression, or sedation. However, when administered with an opioid analgesic, the effects produced by the opioid agonist are promptly reversed. The ability to antagonize opioids at all of the different opioid receptors makes naloxone useful for the treatment of opioid overdose. Naltrexone has a similar profile, but it is orally active and has a significantly longer half-life.



(3)

R = CH_2CHCH_2



(4)

R = 
The quest for compounds that combined the analgesic properties of morphine, were nonaddictive and lacked side effects, led to the development of the drugs that have both agonist and antagonist activities. Nalbuphine [CAS: 20594-83-6] $C_{21}H_{27}NO_4$ and buprenorphine [CAS: 52485-79-7] $C_{29}H_{41}NO_4$ are semisynthetic materials derived from oxymorphone and thebaine [CAS: 115-37-7] $C_{19}H_{21}NO_3$ respectively, whereas pentazocine [CAS: 359-83-11] $C_{19}H_{27}NO$ and butorphanol [CAS: 42408-82-2] $C_{21}H_{29}NO_2$ are benzomorphan and morphan derivatives. Although structurally similar, they display different receptor affinities: pentazocine is a weak μ-antagonist, but a strong agonist of the κ-receptor; nalbuphine is a competitive antagonist for the μ-receptor, blocking the effects of the morphinelike drugs, but is a partial agonist for the κ and ς receptors; and buprenorphine is a partial agonist for the μ-receptor.

Pharmacologically, the effects of these drugs resemble those of opioid agonists. All four have analgesic potency equal to or greater than morphine and, like morphine, they cause respiratory depression. A ceiling effect is reached, however, above which increased doses do not increase respiratory depression or do not produce proportionally greater depression. Buprenorphine causes a slow onset of the depression, and once the effects have begun, naloxone does not readily reverse the symptoms, suggesting that buprenorphine dissociates very slowly from opioid receptors. In all of these drugs except buprenorphine, high doses induce withdrawal symptoms in opioid dependent patients.

Other Analgesic Agents

Most analgesic agents rely on agonism of the μ receptor for their activity, however the ability of the κ and δ receptors to induce analgesia is also well documented. Some nonmorphine analgesics which may preferentially bind to κ and δ receptors are acetorphan [81110-73-8], $C_{21}H_{23}NO_4S$; thiorphan [76721-89-6], $C_{12}H_{15}NO_3S$; and spiradoline [87173-97-5], $C_{22}H_{30}Cl_2N_2O_2$.

Antiinflammatories and Antipyretics

Most of the time, the powerful analgesia supplied by morphine and the other opioid analgesics is not needed. Rather, a mild analgesic, such as aspirin, the most commonly employed analgesic agent, can be used for the treatment of simple pain associated with headaches, minor muscle pain, mild trauma, arthritis, cold and flu symptoms, and fever.

Aspirin, [CAS: 50-78-2] $C_9H_8O_4$ the oldest of the nonsteroidal antiinflammatory drugs (NSAIDs), is a member of the salicylate group. Salicyclic acid, isolated in 1838 from willow bark, was commonly used throughout the Middle Ages for the treatment of headaches. Its therapeutic benefits were well known even to Hippocrates. Many derivatives have been prepared to reduce the irritation associated with the pure acid. The most common form is acetylsalicyclic acid [CAS: 50-78-2]. See also **Asprin**.

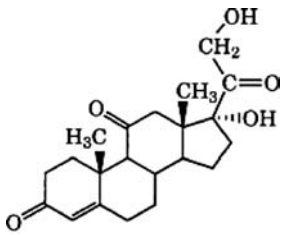
Aspirin's pain relief results, not through direct action on the central nervous system, but rather through peripheral action. It has been proposed that aspirin and aspirinlike drugs inhibit the enzymatic production of prostaglandins, a group of endogenous agents which are well known to cause erythema, edema, pain, and fever. Aspirin does not act as a prostaglandin receptor antagonist; rather it blocks the cyclooxygenase enzymecatalyzed conversion of arachidonic acid [CAS: 506-32-1], $C_{20}H_{32}O_2$, to cyclic endoperoxides, a prostaglandin precursor.

The action of endogenous pyrogens on the hypothalamus produces fever, because of a readjustment in the central set point controlling the body's internal temperature. Salicylates and other NSAIDs achieve their antipyretic effect by controlling the prostaglandin-induced release of pyrogens.

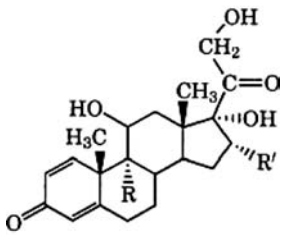
A second class of NSAIDs, the so-called coal-tar analgesics, are derived from acetanilide. Although it is no longer used therapeutically, its analogues, phenacetin and the active metabolite, acetaminophen, are effective alternatives to aspirin. They have analgesic and antipyretic effects that do not differ significantly from aspirin, but they do not cause the gastric irritation, erosion, and bleeding that may occur after salicylate treatment. In contrast to aspirin, however, they are not cyclooxygenase inhibitors and have no antiinflammatory properties. Clinically, acetaminophen is preferred over phenacetin, because it has less overall toxicity.

A nonprescription analgesic is the aryl propionic acid, ibuprofen, which offers significant advantages over aspirin. Ibuprofen, a cyclooxygenase inhibitor, displays good antiinflammatory activity. It is more potent than aspirin and has a lower incidence of gastrointestinal irritation, although at high doses or chronic exposure, gastric irritation, as well as some renal toxicity, has been observed. Ibuprofen is more effective than propoxyphene in relieving episiotomy pain, pain following dental extractions, and menstrual pain.

The adrenal cortex produces steroidal hormones that are associated with carbohydrate, fat, and protein metabolism, electrolyte balance, and gonadal functions. One of these, cortisone, $C_{21}H_{28}O_5$ (5), demonstrated a remarkable ability to relieve the symptoms of inflammatory conditions. Other glucocorticoid steroids, such as dexamethasone, $C_{22}H_{29}FO_5$ (6, R=F, R′=CH_3), and prednisolone, $C_{21}H_{28}O_5$ (6, R=R′=H), also have antiinflammatory properties.



(5)



(6)

These steroids are capable of preventing or suppressing the development of the swelling, redness, local heat, and tenderness which characterize inflammation. See also **Steroids**.

Unfortunately steroids merely suppress the inflammation while the underlying cause of the disease remains. Another serious concern about steroids is that of toxicity. The abrupt withdrawal of glucocorticoid steroids results in acute adrenal insufficiency. Long-term use may induce osteoporosis, peptidic ulcers, the retention of fluid, or an increased susceptibility to infections. Because of these problems, steroids are rarely the first line of treatment for any inflammatory condition, and their use in rheumatoid arthritis begins after more conservative therapies have failed.

ANALOG. 1. A form of data display in which values are shown graphically. 2. A form of computing in which values are represented by directly measurable quantities, such as voltage or resistance. Analog computing methods contrast with digital methods in which values are treated numerically. See also **Analog Computer**.

ANALOG COMPUTER. A computer that solves problems by physical analogy. The computer translates temperature, flow, speed, altitude, voltage, and other physical variables into related electrical quantities and uses electrical equivalent circuits as an analog for the physical phenomenon being investigated. On an analog computer, for example, physical characteristics, such as weight or temperature are represented by voltage. Voltage is the electrical analog of the variable that is being analyzed. The variable itself can be electrical as well as hydraulic or pneumatic. Scale factors relate voltages in the computer to the variable in the problem being solved.

Components of the computer may be designed to operate within any fixed output voltage range. However, only two ranges are in wide use: ±100 volts and ±10 volts. All computer variables are scaled to lie within one of these ranges. For example, a temperature which varies from 0 to 1000 °C is represented on a 100-volt computer by a voltage varying from 0 to 100. The scale factor would be 1/10 volt per °C.

Although analog computers still find application for certain needs, the practice for several years has distinctly reflected a preference for digital computers. For example, the slide rule (an analog computer) was for many decades the "right hand" of engineers and scientists. Although still used on occasion, the slide rule essentially has been displaced by desk calculators, pocket calculators, and personal computers.

ANALOG INPUT. This term is used to describe an assembly of equipment (subsystem) for performing the selection of the analog signal to be sampled, modification or conditioning of the analog signal, analog-to-digital conversion to provide a digital representation, and the necessary digital controls for subsystem control and communication with a digital computer. Generally included in this assembly are signal conditioners, such as attenuators and filters, analog signal multiplexers, amplifiers, analog-to-digital converters, and the control logic. Check alphabetical index.

For data-acquisition or process-control computers, there are two fundamental analog-input subsystem types. However, within each of these basic configurations, there are numerous variations possible as dictated by the use of different kinds of multiplexers, amplifiers, and analog-to-digital converters. Cost and performance are the usual predominating factors in selection. The two major subsystem types are: (1) high-level, and (2) low-level systems.

High-Level Analog-Input Subsystems: High-level signals typically are in the range of 0 to ±10 volts. These are connected to the subsystem input terminals of a configuration of the type shown in Fig. 1. Including

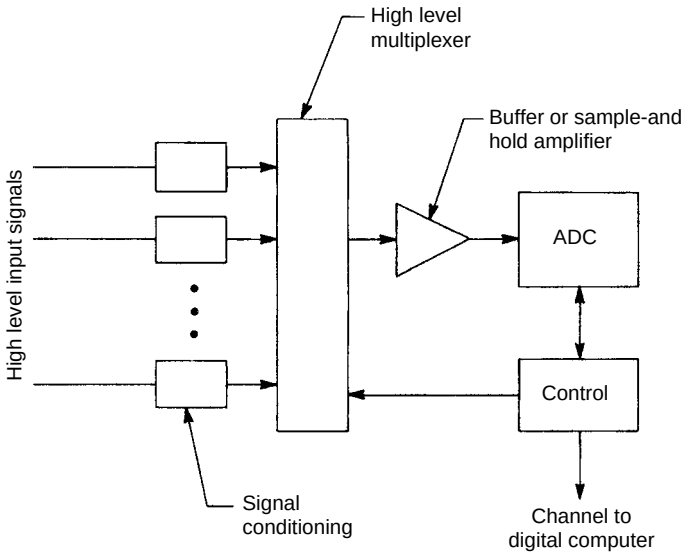

Fig. 1. Schematic diagram of high-level analog-input subsystem.

filtering, limiting to protect the analog-input subsystem from overvoltage, and attenuation, the signal conditioning of signals is performed on a *per-channel* basis. The multiplexer selects the signal to be converted and is under the control of the subsystem control logic. Isolation between the analog-to-digital converter and the input-signal source is provided by a buffer amplifier. A sample-and-hold amplifier may be used to reduce aperture-time errors. The buffer amplifier sometimes is included as an integral part of the analog-to-digital converter. The timing and sequencing of the subsystem operation is transmitted by the control logic, which also transmits the digital value to the digital computer.

Usually configurations of these subsystems are single-ended, although some differential systems are obtainable. The latter are more costly, but offer easier installation because noise and ground loops are less serious. Reduction of the latter problems is important particularly in the case of high-speed, high-resolution applications and where input signals must come from signal sources a considerable distance from the subsystem.

Solid-state switches, capable of sampling signals at very high rates, normally are used in the analog multiplexer. Both bipolar transistors and field-effect transistors are used. Bipolar transistor switches restrict levels to a high level because of voltage-offset errors. The most common analog-to-digital converter used is of the successive-approximation type, since its speed matches the solid-state multiplexer characteristics. For lower-speed applications, ramp and integrating-ramp analog-to-digital converters can be used.

Timing and channel communications functions are provided by the control logic. The digital computer normally initiates a control word, specifying one or more input addresses, to commence operation of the subsystem. The control unit selects the appropriate multiplexer switches. After a predetermined delay time, the control unit provides a "start convert" signal to the analog-to-digital converter. The latter operates asynchronously with respect to the computer and, at the end of the conversion, signals the control logic. Prior to transmitting the result back to the digital computer, the control unit may reformat the output word from the analog-to-digital converter, that is, adding parity bits or converting from parallel to a serial form. It may also collect some or all of the results in a buffer storage where they are available to the computer on demand.

The characteristics of the sampling subsystem are determined by the type of multiplexer, amplifier, and analog-to-digital converter used. Under controlled operating conditions, a total measurement error of less than 0.05% of full scale is desirable.

Subsystems of the type just described have been used in numerous high-speed data-acquisition applications, including hybrid computation and rocket test stand monitoring, as well as for general research. These uses typically have wide channel-bandwidth requirements, high-level signals, and/or a relatively small number of signals. Because the configuration is not adapted to the handling of low-level signals, it is not used widely for process control. For applications involving only a few data points, a high-speed low-level system can be achieved by adding a high-gain amplifier for each input signal.

Low-Level Analog-Input Subsystems: Systems of this type are similar to the high-level system just described with the exception of the use of a time-shared low-level amplifier. See Fig. 2. In operation, the input signals are conditioned and multiplexed by a low-level multiplexer. Before conversion into a digital representation by the analog-to-digital converter, the multiplexer output is amplified by a time-shared amplifier. Measurement accuracy for the total system for a 50-millivolt signal range typically is 0.1%, with a resolution of 10 to 14 bits.

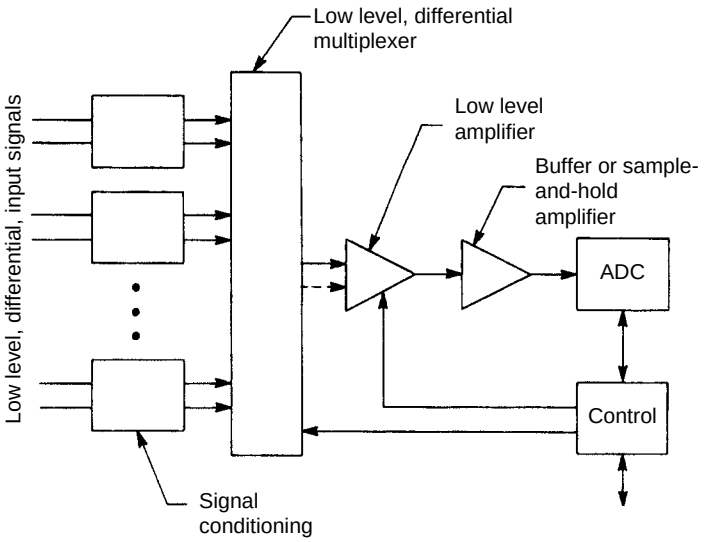

Fig. 2. Schematic diagram of low-level analog-input subsystem.

The low-level signals generally are less than 100 millivolts and often as low as 10 mV full scale. Thus, this type of subsystem usually provides a differential-signal input. See also **Differential-Mode Voltage**. The multiplexer and signal-conditioning circuits are differential. The amplifier may or may not be differential, depending on the type of multiplexer used. A single-ended amplifier may be used where the multiplexer provides common-mode isolation, such as a transformer-coupled multiplexer. The output of the amplifier and the analog-to-digital converter input are single-ended in most cases.

Differential-multiplexer configurations for low-level uses most commonly are the double-pole single-throw differential, flying-capacitor, and transformer-coupled designs. Switching devices normally are dry-reed relays, field-effect transistors, or mercury-wetted contact relays. Field-effect transistor switches can be applied for very high speeds. Electromechanical devices are limited to about 300 samples/second or less. In any case, however, subsystem speed normally is limited to less than 10,000 samples/second because of amplifier performance. With the proper selection of multiplexer configuration and the capabilities of the amplifier, common-mode voltages up to several hundred volts will not affect the acceptable performance of the system. However, where solid-state switches are used in multiplexers, the tolerance is usually limited to something less than 30 volts of common-mode voltage.

In the design of Fig. 2, a differential or single-ended amplifier may be used, depending on the multiplexer characteristics. In some cases, the amplifier will have a fixed gain. In other instances, the control logic may select the gain, either automatically or under control of the computer program. Where a differential amplifier is used, the common-mode tolerance of the amplifier is critical to determining the common-mode rejection of the subsystem. Low-level applications also require that amplifier noise be kept to a minimum.

The design configuration just described has been used in process control and large data-acquisition systems. Such uses typically have low channel-bandwidth requirements and a large number of low-level signals. The time-shared amplifier provides the system with a cost advantage as compared with an amplifier-per-channel type system. The low band-width application

characteristic makes it possible to use the limited system-sampling speed in numerous applications.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ANALOG MULTIPLEXER. An array of analog switches used for the selection of one of several analog signals for transmission to subsequent devices in a data acquisition subsystem. Multiplexers most typically are used for signal selection prior to amplification and conversion to digital form in time-shared subsystems. An analog multiplexer used in the analog-input subsystem of a data-acquisition system is shown schematically in Fig. 1. Multiplexers are not confined to data-acquisition systems, but are used in audio-switching networks in telephony. The particular hardware configuration varies considerably with the nature of the signals and their manipulation. See Fig. 2.

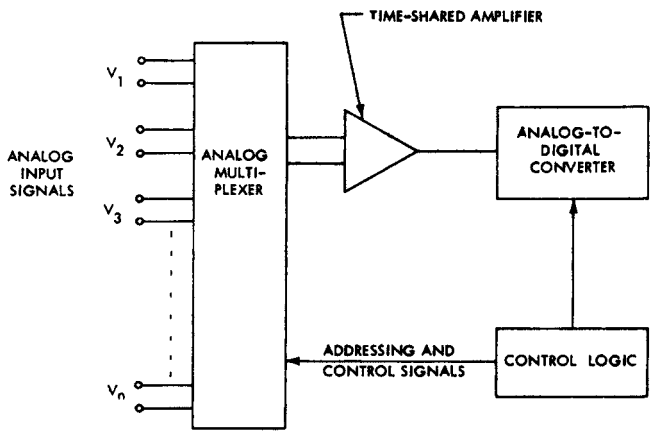

Fig. 1. Location of analog multiplexer in analog input system.

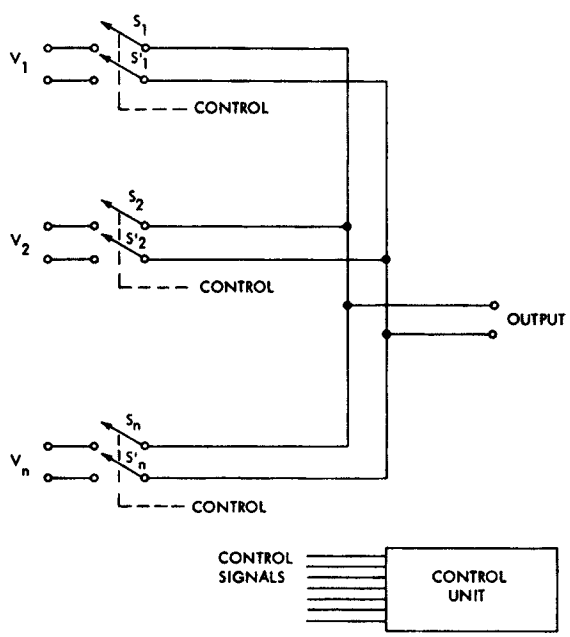

Fig. 2. Generalized configuration of analog multiplexer.

The control unit supervises switch selection. Where the multiplexer is differential, two or three switches are required for each input signal. Where the multiplexer is single-ended, only one switch per input is required, using a common ground to complete the circuit for all input signals. Although the control unit varies with particular applications, its primary function is to furnish the signals required to select or address the various switches in the multiplexer at the proper time. The logic in the control unit or a command from a computer will determine the particular address to be selected. In some cases, the switches may be selected sequentially under control of a ring counter circuit in the control unit. Or, the selection of each address may require a data word from the computer or micro-programmed control unit.

The control unit also furnishes timing for the multiplexer and associated equipment. Usually, the analog-to-digital (A/D) converter cannot commence a conversion instantly after selection of the multiplexer switch. A time delay is required to permit actuation time of the switch, for settling of the amplifier, and for the dissipation of other transients. Counters or delay circuits in the control unit usually furnish the required timing signals.

Several types of solid-state or electromechanical analog switches may be used in the multiplexer. Types of electromechanical switches used are mercury-wetted contact relays, dry-reed relays, and crossbar switch assemblies. Of the solid-state switches, most often field-effect transistors are used. For special applications, diodes, bipolar transistors, and silicon-controlled rectifiers may be used.

Among the major performance characteristics of an analog multiplexer are accuracy, sampling speed, and noise. Common-mode rejection ratio also is important in the instance of a differential multiplexer. The features of the multiplexer switching device mainly determine sampling speed. The electromechanical devices, such as mercury-wetted contact relays and dry-reed relays, usually are limited to about 250 samples/second. Bipolar and field-effect transistors can provide very high sampling speeds. Although a switch may close rapidly, a time interval must be provided to permit transients to dissipate prior to conversion of the multiplexer output signal to digital form. In the case of the mercury-wetted relay, the actual switch-closing time is in the range of 1 millisecond, but there may be a noise transient which will persist at levels in excess of 10 microvolts for perhaps 5 milliseconds or even longer. Where a noise level of this magnitude cannot be tolerated, a delay is required between switch selection and conversion initiation. Noise considerations also effect solid-state switches, but noise duration times are generally much shorter.

Careful consideration must be given to possible errors that a multiplexer can contribute to the operation of a digital-data acquisition subsystem. Leakage currents associated with the "off" switches will, in the case of solid-state switches, flow through the source impedance of the channel being sampled by the "on" switch and also through the multiplexer load impedance. Offset in the voltage being sampled thus can be caused by these currents. Even though leakage current from a single switch may be small (considerably less than a microampere), an appreciable error can result from the cumulative effect of all the switches that are connected to the common multiplexer output bus.

Inasmuch as the field-effect transistor does not show an offset voltage in the "on" condition, it may be used for multiplexing low-level signals. It should be noted, however, that some field-effect transistors show a significant "on" resistance and, because of source loading effects, can introduce errors. Further, the "on" resistance increases the effect of leakage currents as previously described. This may increase the output-signal rise time.

Where differential multiplexers are used, the common-mode rejection ratio is important. This factor is determined by leakage impedances between the switch-signal path and the drive circuit. Further, the maximum common-mode voltage that which may be applied without causing damage to the multiplexer is determined by the breakdown voltage of the switch. Electromechanical devices have high drive-to-signal path and contact-breakdown voltages. Hence, these devices can be used for multiplexers that will withstand several hundreds of volts of common-mode voltage. Generally, solid-state multiplexers are limited to a common-mode voltage less than 20 to 30 volts. Improvement can be obtained through the use of isolation techniques, such as transformers.

The chances of multiplexer errors increase as the number of input channels in the multiplexer increases. Additional channels decrease the common-mode rejection ratio and also increase the offset resulting from leakage currents. *Sub-multiplexing* or *block switching* are techniques frequently used to minimize these conditions. Block switching entails the use of two levels of multiplexing. The first level is the same as that indicated in Fig. 2. This level furnishes selection of an input signal. The second level of multiplexing is provided at the output of the first-level multiplexer.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

ANALOG OUTPUT. This term is used to describe an assembly of equipment (subsystem) and operations in a process control computer or data-acquisition system with the capability to provide a continuous voltage or current output which can be controlled by a digital computer. Closed-loop control systems, for example, which utilize a digital process control computer require current signals which may have ranges of 4 to 20, 1 to 5, or 10 to 50 milliamperes. These signals, in turn, are used for controlling process actuators, such as valve positioners. For the generation of visual displays, recorders and cathode-ray tubes require similar analog signals.

The digital-to-analog (D/A) converter is the principal component of the analog-output subsystem. Simply defined, a D/A converter is an electronically controlled attenuator network and a constant reference source. Digital-input signals received by the D/A converter activate analog switches, which determines the attenuation factor of a passive network. Either electromechanical or solid-state switches may be used. The input to the attenuator network is a constant-voltage or -current source. The output of the network is proportional to the attenuator switch settings and, thus, to the digital-input signals.

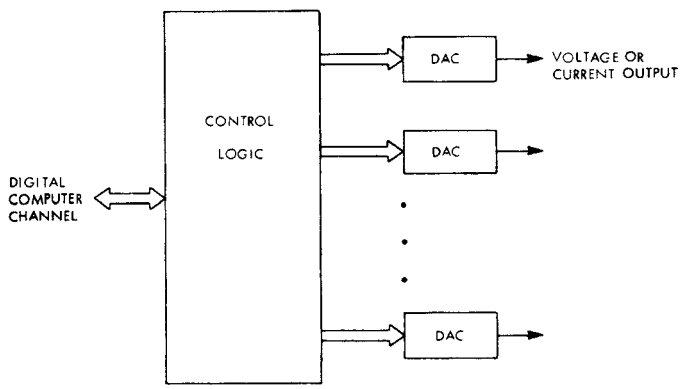

Fig. 1. Basic analog-output subsystem.

Connection of the D/A converter to the digital computer is through control logic. The latter provides addressing for each D/A converter and also the required control and timing signals. Shown in Fig. 1 is an analog-output system of the kind used in process control computer or data acquisition systems. The digital computer, via digital-control words, specifies which D/A converter is to be adjusted. Another digital data word carries the desired output value. The address information is decoded in the control logic. The digital data also are routed to the input of the addressed D/A converter. This setting of the input switches of the D/A converter provides the desired analog-output value. The kind of subsystem shown is frequently used where the analog-output value is changed often, at a rate in excess of 1000 samples/second. This subsystem configuration can adjust many D/A converters at rates exceeding 100,000 samples/second. The resolution of the D/A converters used for applications of this type usually ranges from 8 to 13 bits. The total error of the output voltage, under controlled operating conditions, may be less than 0.01%.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ANALOGS. Two observed states of the atmosphere that are very close by some measure, also applied to states of a model.

Formal measures of closeness include anomaly correlation, root-mean-square distance, and covariance. Usually one expects analogs to occur only during the same time of year. Atmospheric analogs that are close compared to current levels of observational error are unlikely to be found unless one studies a single variable confined to a very small area ($\leq$1000 km radius), or otherwise reduces the degrees of freedom to a very small number ($\leq$3). Analogs have a practical application in specifying the surface weather from a 3D atmospheric state produced by NWP and in short- term climate prediction for forecasts ranging from a month to several seasons. Analogs are also of interest in research related to predictability, short-term forecasts and error growth, cluster analysis, and estimates of dimensionality of the atmospheric attractor. When natural analogs are poor, improvements have been sought by combining several of them, by using anti-analogs (antilogs), and by constructing an artificial close analog by some objective weighted averaging of a set of previously observed states (constructed analogs).

ANALOG SWITCH. This term applies to a large family of switches that are designed for switching analog signals and normally implies high accuracy and high resolution. In data-acquisition and instrumentation systems, the most important switch characteristics are speed, voltage and current errors, "on" and "off" resistance, and noise.

Electromechanical analog switches, including mercury-wetted contact and dry-reed relays, usually have a lower "on" resistance and a higher "off" resistance than most solid-state switches. Also, because of excellent isolation between drive and signal circuits, electromechanical switches have no inherent voltage offset and leakage currents. Disadvantages include their slow performance as compared with solid-state switches and the production of noise by the switching action, a condition which tends to persist for an appreciable period.

Solid-state switches on the other hand are high-speed devices and with "on" and "off" resistances, compared with electromechanical switches, as described above. Where a *pn* junction is part of the signal path, as in a bipolar transistor, the switch will show an inherent voltage offset. The leakage currents between drive and signal paths also are larger in bipolar transistors as the result of less isolation between drive and signal. Field-effect transistors display leakages comparable with those of electromechanical switches. Noise results from switching action mainly because of coupling of the drive signal into the signal path by way of inter-electrode capacitance. Even though the noise magnitude may be appreciable, decay to a negligible value occurs much more rapidly than in electromechanical switches.

Use of the major classes of analog switches is summarized as follows:

Relays and Other Electromechanical Devices — used for low-level signals (less than 1 V full-scale) and multiplexing speeds generally not exceeding 250 samples/second.

Field-Effect Transistors — used for low-level applications at higher speeds. Limited in common-mode-voltage handling capability as result of lower breakdown voltages.

Bipolar Transistors — used for high-level signals, but with appropriate circuitry for compensation of offset voltages; also may be used for low-level signals. They have been used less frequently in recent years due to improvements in field-effect transistor technology.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ANALOG-TO-DIGITAL CONVERTER. Abbreviated A/D converter or ADC. A device that provides a digital representation of an analog quantity. Examples of the latter include voltage, current, or a position. There are two principal types of A/D converters used in data-acquisition systems: (1) electromechanical, and (2) electronic converters. The electromechanical types sometimes are referred to as shaft- or position-to-digital encoders. Generally, they are comprised of a mask attached to the moving mechanical element, along with a means to read the information on the mask. Magnetic, optical, and electrical means are used for reading. Where electrical sensing is used, the mask may consist of a conducting pattern on an insulated substrate. The code represented by the mask pattern is read by means of fixed conducting brushes which are in contact with the pattern. Optical sensors use a light source and photodetectors, whereas magnetic sensors employ inductive-pickup coils.

The sensing means has a finite width. Consequently, there may be an ambiguity in the digital output. This would result, for example, where a conducting brush would be in contact with two adjacent portions of the mask pattern at the same time. Ambiguity can be avoided through the use of special codes and ingenious arrangements of the sensing detectors. Gray code, where only one bit in the digital output changes at any given time as the position of the mask is varied, may be used. A V-scan technique also can be used. In the latter, two detectors are used for each track on the mask. With appropriate decoding of the outputs from the pairs of detectors, an unambiguous digital representation will result.

Electronic A/D Converters: Two classes are used: (1) the input quantity, usually a voltage or current, is converted into another form, such as a frequency or a pulse duration. This intermediate quantity then is measured to yield a digital representation of the input signal. (2) the input is

compared directly with a known reference signal which can be varied under control of the A/D converter logic. Several subclasses of A/D converters are obtainable within these two broad classes.

The principal techniques most frequently employed in process control and data-acquisition computers are (1) ramp; (2) integrating-ramp; (3) voltage-to-frequency; (4) successive-approximation; and (5) parallel-serial methods. Check alphabetical index for further coverage. With reference to the two broad classifications, the ramp, integrating ramp, and voltage-to-frequency methods involve the conversion of the input signal into an intermediate quantity before measurement. The successive-approximation and parallel-serial methods are direct-comparison methods.

Numerous cost/performance trade-offs are involved in the selection of the most appropriate A/D converter for a given process control or data-acquisition system. The characteristics are summarized as follows:

Ramp and Voltage-to-Frequency Converters—relatively slow (require serial counting); used at speeds less than several thousand samples/second; usually resolutions of less than 12 bits.

Successive-Approximation Converters—useful up to about 100,000 samples/second at resolution of 16 bits. Useful up to more than 250,000 samples/second at resolution of 8 bits or less.

Parallel-Serial Converters—high-speed uses requiring conversion rates in excess of 100,000 samples/second; resolution of 8 to 14 bits.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ANALOGY (Dynamics). Many dynamical systems, especially mechanical and acoustical ones, can be analyzed by analogy to electrical systems. This is true because these various systems possess certain common attributes such as energy, power, frequency (of vibration, rotation, or alternation), and because equations for calculating these and other quantities can be written in terms of variables that are closely analogous. For example, electromotive force in an electrical system is strictly analogous to force in a mechanical rectilinear system, to torque in a mechanical rotational system, and to pressure in an acoustical system. Again, current in an electrical system is closely analogous to linear velocity in a mechanical rectilinear system, to angular velocity in a mechanical rotational system, and to volume current in an acoustical system.

To show the applications of these analogies the following relationships are given for the four systems cited. Note that a dot above a quantity denotes its first derivative with respect to time.

The kinetic energy T_{KE} stored in the magnetic field of the electrical circuit is

$$T_{KE} = \tfrac{1}{2}Li^2$$

where L = inductance, in abhenries, and i = current through the inductance L, in abamperes.

The kinetic energy T_{KM} stored in the mass of the mechanical rectilinear system is

$$T_{KM} = \tfrac{1}{2}m\dot{x}^2$$

where m = mass, in grams, and $\dot{x}$ = velocity of the mass m, in centimeters per second.

The kinetic energy T_{KR} stored in the moment of inertia of the mechanical rotational system is

$$T_{KR} = \tfrac{1}{2}I\dot{\phi}^2\theta$$

where I = moment of inertia, in gram (centimeter)^2, and ϕ = angular velocity of I, in radians per second.

The kinetic energy T_{KA} stored in the inertance of the acoustical system is

$$T_{KA} = \tfrac{1}{2}M\dot{X}^2$$

where $M = \text{m/S}^2$, the instance, in grams per (centimeter)^4
m = mass of air in the opening, in grams
S = cross-sectional area of the opening, in square centimeters
$X = \text{S}\dot{x}$ = volume current, in cubic centimeters per second
$\dot{x}$ = velocity of the air particles in the opening, in centimeters per second

Similar relations hold for potential energy. Thus the potential energy V_{PE} stored in the electrical capacitance of the electrical circuit is

$$V_{PE} = \frac{1}{2}\frac{q^2}{C_E}$$

where C_E = capacitance, in abfarads, and q = charge on the capacitance, in abcoulombs.

The potential energy V_{PM} stored in the compliance or spring of the mechanical rectilinear system is

$$V_{PM} = \frac{1}{2}\frac{x^2}{C_M}$$

where $C_M = 1/s$ = compliance of the spring, in centimeters per dyne
s = stiffness of the spring, in dynes per centimeter (1 newton = 10^5 dynes)
x = displacement, in centrimeters

The potential energy V_{PR} stored in the rotational compliance or spring of the mechanical rotational system is

$$V_{PR} = \frac{1}{2}\frac{\phi^2}{C_R}$$

where C_R = rotational compliance of the spring, in radians per dyne per centimeter, and ϕ = angular displacement, in radians.

The potential energy V_{PA} stored in the acoustical capacitance of the acoustical system is

$$V_{PA} = \frac{1}{2}\frac{X^2}{C_A}$$

where X = volume displacement, in cubic centimeters
$C_A = V/\rho c^2$ = acoustical capacitance, in (centimeters)^5 per dyne
V = volume of the cavity, in cubic centimeters
ρ = density of air, in grams per cubic centimeter
c = velocity of sound, in centimeters, per second

Moreover, the total energy in any of these systems can be found simply by adding the kinetic and the potential energies. These relationships are particularly useful in the facility with which relationships like Kirchhoff's law, and its mechanical and acoustical analog, D'Alembert's principle, can be used in the solution of mechanical or acoustical networks, that is, in various series of springs, gears and acoustical elements such as are found in complex trains of equipment as, for example, reduction gearing, loudspeakers, microphones, phonograph pickups, automobile suspensions, wave filters, and other electromechanical and electro-acoustic transducers. Even the electrical reciprocity and superposition theorems have their analogs for mechanical and acoustical systems.

The construction of electrical analogies is frequently used in the analysis of process and process control performance. The field of fluidics has brought forth some very interesting and helpful applications of the analog technique.

ANALOGY (Physiology). The relationship between body parts having different embryonic and phylogenetic origin, but with the same function. As an example, the wings of insects and the wings of birds are analogous and illustrate the principle of analogy. These wings are used for the same function, flying, but they arise in an entirely different manner in the embryonic development. See **Homology**.

ANALYSIS (Chemical). Analytical chemistry is that branch of chemistry concerned with the detection and identification of the atoms, ions, or radicals (groups of atoms which react as a unit) of which a substance is composed, the compounds which they form, and the proportions of these compounds present in a given substance. The work of the analyst begins

with sampling, since analyses are performed upon small quantities of material. The validity of the result depends upon the procurement of a sample that is representative of the bulk of material in question (which may be as large as a carload or tankload).

The Revolution in Analytical Chemistry — A Perspective. During the last few decades, not many branches of any science have undergone so much change in the equipment and procedures used as has the field of *chemical analysis*. This revolution also has impacted on how the principles of chemistry are taught today. The revolution in analysis also has had wide influence on technology in general because of the far greater accuracy with which chemical determinations can be made. Just a few years ago, analyses that would yield reliable data in the range of a few parts per million (*ppm*) were considered excellent. The accurate reporting of parts per billion (*ppb*) was achieved in the 1960s. With modern analytical instrumentation available beginning in the 1990s, a part per trillion $\left(\frac{1}{10^{12}}\right)$ sensitivity was achieved for some routine analyses, as, for example, in determinations of the dangerous pollutant, *dioxin*. A special tandem-accelerator mass spectrometer now can detect three atoms of ^{14}C in the presence of 10^{16} atoms of ^{12}C in a radiocarbon age dating procedure. (It is interesting to note that a pinhead would occupy a part per trillion of the area of a road from New York to California; 10^{12} molecules of molecular weight 600 weigh only 10^{-9} gram.)

While the impact of vastly improved chemical analysis has been felt by essentially all phases of science, dramatically more precise data have been of notable significance in the area of pollutants and pharmaceuticals. The effects of minute impurities, beyond detection just a few years ago, now can be determined and become the basis for pollution and drug legislation, litigation, etc. In some cases, unfortunately, the long-term effects of impurities in substances and in the environment remains a pseudoscience of statistics. Consequently instrumentally yielded analytical chemical information requires caution and prudence in its application to decision making at a policy level.

Traditional Analytical Chemistry. In the interest of putting modern analytical chemistry in perspective, it is in order to review that long time period (essentially prior to the 1940s) when the subject was divided into two readily understood areas:

1. *Qualitative chemical analysis*, in which one is concerned simply with the identification of the constituents of a compound or components of a mixture, sometimes accompanied by observations (rough estimates) of whether certain ingredients may be present in major or trace proportions.
2. *Quantitative chemical analysis*, which is concerned with the amounts (to varying degrees of precision) of all, or frequently of only some, specific ingredients of a mixture or compound. Classically, quantitative chemical analysis is divided into (a) *gravimetric analysis* wherein weight of sample, precipitates, etc., is the underlying basis of calculation, and (b) *volumetric analysis* (titrimetric analysis) wherein solutions of known concentration are reacted in some fashion with the sample to determine the concentration of the unknown. Obviously, the Figure from either gravimetric or volumetric determinations are convertible and the two methodologies frequently are combined in a multistep analytical procedure.

Classical laboratory, manual methods conducted on a macro-scale where sample quantities are in the range of grams and several milliliters. These are the techniques that developed from the earliest investigations of chemistry and which remain effective for teaching the fundamentals of analysis. However, these methods continue to be widely used in industry and research, particularly where there is a large variety of analytical work to be performed. The equipment, essentially comprised of analytical balances and laboratory glassware, tends to be of a universal nature and particularly where budgets for apparatus are limited, the relative modest cost of such equipment is attractive.

A Gradual Break from Tradition. One of the first breaks from traditional analytical chemistry was the addition of *microchemical methods*. These methods essentially extended macro-scale techniques so that they could be applied for determinations involving very small (milligram) quantities of samples. These methods required fully new approaches or extensive modifications of macro-scale equipment. Consequently, the apparatus usually was sophisticated, relatively costly, and required, greater manipulative skills. Nevertheless, microchemical methods opened up entirely new areas of research, making possible the determination of composition where the availability of samples, as in many areas of biochemistry, was confined to very small quantities.

A second major break was the introduction of *semi-automated analytical apparatus* that introduced an interim step between (a) macro-scale and microchemical analysis techniques on the one hand and (b) fully instrumented and automated analytical methods on the other hand. Significant design changes in chemical balances that greatly increased the speed of weighing samples and reagents and automatic and self-refilling burettes are examples of ways in which an analytical procedure could be "tooled" to conserve technician power, reduce drudgery, and often contribute to more reliable and precise results.

Another major break was the introduction of *process analyzers*, which moved the chemical control laboratory from a central location in a materials-manufacturing plant to the use of chemical analyzers *on-line*. With this concept, quality control no longer depended upon grab samples, analyzed periodically and thus always behind (time lag) conditions actually occurring in the process itself at any given instant. Many analytical instruments today, at least in principle, are applicable to on-line installation. While thousands of on-line analyzers are in place, usage throughout the processing and manufacturing industries is far from universal. Difficulties in designing and protecting sensitive instrumentation from the very rugged environments encountered on-line continue. Thus, chemical composition is commonly inferred from other related measurements, such as temperature, pressure, and careful chemical analysis of raw materials at the input side and similar analyses of products on the output side. Numerous techniques used for on-line instrumentation are described in this encyclopedia.

Energy — Matter Interactions in Analytical Instrumentation. Modern chemical analyzers, ranging from research and laboratory applications to process control, developed in a rather chaotic manner over several decades. There indeed was no master plan and, in fact, it was not until the late 1950s that a concerted attempt was made to classify analytical instruments in a scientific way. Table 1 is an updated, but abridged version of a summary prepared and first published in 1957.[1] The thrust of the summary is directed toward industrial instrumentation, although it embraces the principal laboratory instruments as well.

Chemical-composition variables are measured by observing the interactions between matter and energy. That such measurements are possible stems from the fundamental that all known matter is comprised of complex, but systematic arrangements of particles which have mass and electric charge. Thus, there are neutrons that have mass but no charge; protons that have essentially the same mass as neutrons with a unit positive charge; and electrons that have a negligible mass with a unit negative charge. The neutrons and protons comprise the nuclei of atoms. Each nucleus ordinarily is provided with sufficient orbital electrons, in what is often visualized as a progressive shell-like arrangement of different energy levels, to neutralize the net positive charge on the nucleus. The total number of protons plus neutrons determines the atomic weight. The number of protons, which, in turn, fixes the number of electrons, determines the chemical properties and the physical properties, except mass, of the resulting atom.

The chemical combinations of atoms into molecules involve only the electrons and their energy states. Chemical reactions involving both structure and composition generally occur by loss, gain, or sharing of electrons among the atoms. Thus, every configuration of atoms in a molecule, crystal, solid, liquid, or gas may be represented by a specific system of electron energy states. Also, the particular physical state of the molecules, as resulting from their mutual arrangement, also is reflected upon these energy states. Fortunately, these energy states, characteristic of the composition of any particular substance, can be inferred by observing the consequences of interaction between the substance and an external source of energy.

[1] Albright, C.M., Jr., "Chemical Composition," in *Process Instruments and Controls Handbook*, D.M. Considine, Editor, McGraw-Hill, New York, 1957. The book is now in its 4th edition (1993).

TABLE 1. INTERACTIONS BETWEEN ENERGY AND MATTER UTILIZED IN ANALYTICAL INSTRUMENTATION

GROUP I — INTERACTIONS WITH ELECTROMAGNETIC RADIATION

Measurement of the quantity and quality of electromagnetic radiation emitted, reflected, transmitted, or diffracted by the sample.

Electromagnetic radiation varies in energy with radiation frequency, that of the highest frequency or shortest wavelength having the highest energy and penetration into matter. Radiation of the shortest wavelengths (gamma rays) interacts with atomic nuclei; x-rays with the inner shell electrons; visible and ultraviolet light with valence electrons and strong interatomic bonds; and infrared radiation and microwaves with the weaker interatomic bonds and with molecular vibrations and rotation. Most of these interactions are structurally related and unique. They may be used to detect and measure the elemental or molecular composition of gas, liquid, and solid substances within the limitations of available equipment.

Emitted Radiation
- Thermally Excited: Optical emission spectro-chemical analysis
  - Flame photometry
- Electro-magnetically Excited: Fluorescence
  - Raman spectro-photometry
  - Induced radioactivity
  - X-ray fluorescence

Transmitted and Reflected Radiation
- X-ray analysis
- Ultraviolet spectro-photometry
- Ultraviolet absorption analysis
- Conventional photometry — transmission colorimetry
- Colorimetry
- Light scattering techniques
- Optical rotation-polarimetry
- Refractive index
- Infrared spectro-photometry
- Infrared process analyzers
- Microwave spectroscopy
- Gamma ray spectroscopy
- Nuclear quadrupole moment

GROUP II — INTERACTION WITH CHEMICALS

Measurement of the results of reaction with other chemicals in terms of amount of sample or reactant consumed, product formed, or thermal energy liberated, or determination of equilibrium attained.

The selectivity inherent in the chemical affinity of one element or compound for another, together with their known stoichiometric and thermodynamic behavior, permits positive identification and analysis under many circumstances. In a somewhat opposite sense, the apparent dissociation of substances at equilibrium in chemical solution gives rise to electrically measurable valence potentials, called oxidation-reduction potentials, whose magnitude is indicative of the concentration and composition of the substance. While individually all the above effects are unique for each element or compound, many are readily masked by the presence of more reactive substances so they can be applied only to systems of known composition limits.

Consumption of Sample or Reactant
- Orsat analyzers
- Automatic titrators

Measurement of Reaction Products
- Impregnated paper-tape devices
- Photometric reaction product analyzers

Thermal Energy Liberation
- Combustion-type analyzers
- Total combustibles analyzers (hydrocarbons and carbon monoxide analyzers)

Equilibrium Solution Potentials
- Redox potentiometry
- pH (hydrogen ion concentration)
- Metal ion equilibria

GROUP III — REACTION TO ELECTRIC AND MAGNETIC FIELDS

Measurement of the current, voltage, or flux changes produced in energized electric and magnetic circuits containing the sample.

The production of net electric charge on atoms or molecules by bombardment with ionizing particles or radiation or by electrolysis or dissociation in solution or the induction of dipoles by strong fields establishes measurable relationships between these ionized or polarized substances and electric and magnetic energy. Ionized gases and vapors can be accelerated by applying electric fields, focused or deflected in magnetic fields, and collected and measured as anelectric current in mass spectroscopy. Ions in solution can be transported, and deposited if desired, under the influence of various applied potentials for coulometric or polarographic analysis and for electrical conductivity measurements. Inherent and induced magnetic properties give rise to specialized techniques, such as oxygen analysis based on its paramagnetic properties and nuclear magnetic resonance, which is exceedingly precise and selective for determination of the compounds of many elements.

Mass Spectroscopy
- Quadrupole mass spectrometry

Electrochemical
- Reaction product analyzers

Electrical Properties
- Electrical conductivity/electrical resistivity
- Dielectric constant and loss factor
- Oscillometry
- Gaseous conduction

Magnetic Properties
- Paramagnetism
- Nuclear magnetic resonance
- Electron paramagnetic resonance

GROUP IV — INTERACTION WITH THERMAL OR MECHANICAL ENERGY

Measurement of the results of applying thermal or mechanical energy to a sample in terms of energy transmission, work-done, or changes in physical state.

The thermodynamic relationship involving the physical state and thermal energy content of any substance permits analysis and identification of mixtures of solids, liquids, and gases to be based on the determination of freezing or boiling points and on the quantitative measurement of physically separated fractions. Useful information can often be derived from thermal conductivity and viscosity measurements, involving the transmission of thermal and mechanical energy, respectively.

Effects of Thermal Energy
- Thermal conductivity
- Melting and boiling point determinations
- Ice point-humidity instrumentation, among others
- Dew point-humidity instrumentation, among others
- Vapor pressure
- Fractionation
- Chromatography
- Thermal expansion

Effects of Mechanical Energy or Forces
- Viscosity
- Sound velocity
- Density and specific gravity

External energy sources used in analytical instrumentation include:

1. electromagnetic radiation
2. electric or magnetic fields
3. chemical affinity or reactivity
4. thermal energy
5. mechanical energy

The interaction of electromagnetic radiation with matter yields fundamental information as the result of the fact that photons of electromagnetic radiation are emitted or absorbed whenever changes take place in the quantized energy states occupied by the electrons associated with atoms and molecules. X-rays (photons or electromagnetic wave packets with relatively high energy) penetrate deeply into electron orbits of an atom and provide, upon absorption, the large quantity of energy required to excite one of the innermost electrons. Thus, the pattern of x-ray excitation or absorption is relative to the identity of those atoms whose orbital electrons are excited, ideally suiting x-ray techniques for determining atoms and elements in dense samples. But, because of the penetrating power of x-rays, they are not suited to the excitation of low-energy states that correspond to outer-shell or valence electrons; or of the inter-atomic bonds which involve vibration or rotation.

In contrast, the relatively longer wavelengths of infrared radiation (photons having relatively low energy) correspond to the energy transformations involved in the vibration of atoms in a molecule as resulting from stretching or twisting of the inter-atomic bonds. Thus, because the penetrating power of electromagnetic radiation varies over the total spectrum, an instrumental irradiation technique can be developed for almost any analytical instrumentation requirement.

The interaction of matter with electric or magnetic fields is widely applied for determining chemical composition. The mass spectrometer, for example, which uses a combination of electric and magnetic fields to sort

out constituent ions in a sample, takes full advantage of this interaction. A simple electric-conductivity apparatus determines ions in solution as the result of applying an electric potential difference across an electrolyte.

The use of chemical reactions in analytical instrumentation essentially extends the fundamental techniques of older laboratory analytical methods.

Numerous analytical instrumentation techniques involve interactions between mechanical and thermal energy with matter. All of these interactions are summarized in the accompanying table.

Targets of Analytical Instrumentation. Some authorities feel that less emphasis and even abandonment by some educational institutions of the traditional qualitative-analysis (wet basis) course represents the loss of a great learning experience in the fundamentals of chemistry. Generally, for teaching purposes, the course is limited to inorganic substances. Practically all of the fundamentals of inorganic chemistry are called upon in the execution of qualitative analysis. Thus, in addition to serving as an effective analytical procedure, the method is an effective teacher.

The first important step is that of putting the sample (unknown) into solution. For metals and alloys, strong acids, such as HCI, HNO_3, or aqua regia may be used. If the material is not fully dissolved by these acids, it should be fused, either with sodium carbonate (alkaline fusion) or potassium acid sulfate (acid fusion). Care should be exercised to make certain that no portion of the unknown is volatilized and thus lost during these procedures.

The next step is the detection of the cations of the metals. For this purpose, the solution should be treated with HNO_3, by evaporation and redissolving if necessary, to remove other acid radicals, so that nitrate is the only anion present in the solution. Then, a systematic procedure is followed for separation of groups of the cations. Such schemes of separation have been devised for all the metals found in nature. A shortened plan, which applies to 24 of the commonly occurring metals and ammonium, has been known and practiced for many years. This plan consists of the separation of the 24 metals into five groups. Further details of the procedure are given in the 6th Edition of this encyclopedia.

Criteria for Selecting Appropriate Analytical Method. These include (1) sensitivity, (2) specificity, (3) speed, (4) sampling methodology required, (5) simplicity (translated into terms of expertise needed), and, of course, cost as traded off against the other criteria.

Sensitivity, as previously mentioned, has improved almost astoundingly over the past few years. Of course, great sensitivity is not always needed, with the ppm and ppb levels well serving many industrial and laboratory requirements. Most frequently, sensitivity is closely related to cost. Sensitivity is also closely related to accuracy, i.e., sensitivity of a reliable, repeatable nature. See also separate entries on **Accuracy**; **Repeatability**; **Reproducibility**; and **Sensitivity**. Sensitivity depends on how well the target of measurement can be transduced into some reliable signal from which the instrument can create a display and/or record. The absorption or emission of photons is the basis of many spectroscopic analytical methods, such as x-ray, ultraviolet, infrared, nuclear magnetic resonance, Raman, Mossbauer, etc., as well as of charged particles, which serve as the basis for electron and mass spectrometry and of the electrochemical, flame ionization, etc. used in chromatography. Through the use of intense energy sources, such as lasers, synchrotron radiation, and plasmas, the efficiency of converting (transducing) the objective parameter of analysis (*analyte*) is greatly improved. McLafferty reports that efficiencies approaching 100% have been experienced for resolution-enhanced multi-photon ionization of atomic and molecular species. Multiplier detectors can respond to the arrival of a single photon or ion. Such methods can detect, for example, a single cesium atom or naphthalene molecule.

Specificity is an ever-present criterion because there are indeed few analytical techniques that detect single species without careful tuning. Frequently, filtering techniques must be used as a means of narrowing the range of detection. See **Infrared Radiation**; and **Ultraviolet Spectrometers**.

Speed. The rapidity with which an analysis can be performed and utilized (including interpretation, whether manual or automatic) is particularly important in industrial chemical analysis. In a laboratory setting, this may not be quite so urgent, but even then time is a major criterion where, in most cases, special personnel are held up in other activities, awaiting the results of an analysis. Frequently higher cost can be justified on the basis of less time and lower personnel costs per analysis made.

One of the principal contributions of electronic data processing over the past several years in terms of chemical analysis is the saving of manual effort in interpreting analytical data. Special techniques, such as Fourier transform, have increased speed (as well as sensitivity) by orders of magnitude in connection with infrared, nuclear magnetic resonance, and mass spectroscopy. Of course, for on-line process analyses, essentially instantaneous interpretation is required to provide the proper error signal that is used to position the final control element (valve, feeder, damper, etc.).

Sampling for analysis is sometimes considered a secondary criterion in the selection of an analysis system. In the laboratory or on the process, sampling often is the practical key to success. The entire result can depend upon obtaining a *truly representative* sample and the sampling methodology used varies widely with the materials to be analyzed. Sampling of solids, such as coal, metals, etc. differs markedly from sampling for fluids. Particularly in process analyses, where the environment varies and contrasts markedly with the usual laboratory conditions, a gas or liquid will require filtering and temperature and pressure conditioning — so that the composition detector will consistently be exposed to the material in question under the same physical conditions.

ANALYSIS (Meteorology). 1. In synoptic meteorology, a detailed study of the state of the atmosphere based on observations, usually including a separation of the entity into its component patterns and involving the drawing of families of isopleths for various elements.

Thus, the analysis of synoptic charts may consist, for example, of the drawing and the interpretation of the patterns of wind, pressure, pressure change, temperature, humidity, clouds, and hydrometeors, all based on observations taken or forecast simultaneously.

2. A procedure to project the state of the atmosphere (or any system) as known from a finite set of imperfect, irregularly distributed observations onto a regular grid or to represent the atmospheric state by the amplitude of standard mathematical functions.

The grid and/or functional expansion allows for subsequent forecasts by numerical integration or for easy diagnostic study. An analysis may be looked upon as a space–time interpolation system. Essential ingredients of analysis are a background field, usually a short-range forecast although persistence and climatology are options, a forecast model, knowledge of the relative error of the many different observational platforms employed as well as knowledge of the error in the background field, and the spatial covariance of the various errors. Real time computational considerations generally limit the complexity of methods used. Historically important is the subjective hand analysis, that is, drawing isobars on a map given mean sea level pressure at a set of observing stations. Most analysis systems in the past have been at best 3D spatial analyses; time–space analysis systems have recently emerged at operational prediction centers. A long series of analyses is of great utility for studying the behavior of the atmospheric climate system.

AMS

ANALYSIS OF COVARIANCE. A generalization of Analysis of Variance to the case where more than one variable is observed on each member of the sample. Suppose, for example, there are two variables x and y such as the scores on a test of a group of students before undergoing a course of instruction (x) and after the course is completed (y). The final performance y will be influenced both by the course and the knowledge of the student at the outset, represented by x. To disentangle these effects y is regressed on x and the residual $y - bx$ computed, b being the regression coefficient. This residual should, in suitable circumstances, represent the effect of the course regardless of initial knowledge and the set of residuals can be subjected to variance analysis if the students are classified in any way. More generally, if x is a variable unaffected by classification or treatment in an experiment, its effect on y can be extracted from y and the residuals analyzed in the ordinary way; and so for several variables of type x, which can also be abstracted from y by the use of a regression equation.

SIR MAURICE KENDALL, International Statistical Institute, London

ANALYSIS OF VARIANCE. In statistics, a technique for segregating the causes of variability affecting a set of observations. Consider a simple case in which a number of observations are taken on members falling into different classes (for example the yields of a number of plots of wheat, groups of which are subjected to different fertilizer treatments). The problem is whether the yields differ from group to group or, on the other hand, differ only as random variations from a homogeneous population. The matter is decided by comparing the sum of squares of mean yields of groups about the overall mean of all plots with the aggregated sum of squares of observations within groups about their respective group means. On the assumption that the variation is normal (Gaussian) an exact test of significance can be applied to decide whether the difference is great enough to justify the conclusion that group differences are real.

The method can be generalized to much more elaborate situations where the classifications are more complex, especially in experimental designs which are carefully balanced so that analyses of variance are easy to apply.

The technique is frequently referred to as ANOVA.

SIR MAURICE KENDALL, International Statistical Institute, London

ANALYSIS (Organic Chemical). Various techniques are used in the chemical analysis of organic substances both in microanalysis and macro laboratory procedures. As contrasted with the determination of total carbon content or the amounts of other specific chemical elements, the representative analytical techniques described here are directed toward the determination of presence and amount of various functional groups (radicals). These groups also are described elsewhere in this volume and, in several instances, additional analytical procedures are related.

(1) The *carboxyl group* is determined by titration with standard sodium hydroxide solution, using phenolphthalein as the indicator, by the reaction

$$\mathrm{RCOOH + NaOH \longrightarrow RCOONa + H_2O}$$

(2) The *hydroxyl group* is determined by reaction with acetic anhydride on heating in a sealed tube by the reaction

$$\mathrm{ROH + (CH_3CO)_2O \longrightarrow ROOCCH_3 + CH_3COOH}$$

The amount of hydroxyl group present is found by titrating the resulting acetic acid (CH_3COOH) with standard sodium hydroxide, as in (1).

(3) The *acyl group* (−COOR) in esters and amides is determined by hydrolysis in alcoholic sodium hydroxide solution, followed by ion exchange with an acidic resin. The carboxylic acid formed is then titrated with standard sodium hydroxide, as in (1). The reactions are

$$\underset{\text{Ester}}{\mathrm{RCOOR' + NaOH}} \longrightarrow \mathrm{RCOONa + R'OH}$$

or

$$\underset{\text{Amide}}{\mathrm{RCONHR' + NaOH}} \longrightarrow \mathrm{RCOONa + R'NH_2 + H_2O}$$

$$\mathrm{RCOONa + Resin\text{-}SO_3H \longrightarrow RCOOH + Resin\text{-}SO_3Na}$$

(4) The *carbonyl group* is determined by a reaction with 2,4-dinitrophenyl hydrazine which precipitates the 2,4-dinitrophenyl hydrazone

of the aldehyde or ketone, which is then filtered off, dried, and weighed. The reaction is

$$RR'CO + H_2NNHC_6H_3(NO_2)_2 \longrightarrow RR'C{:}NNHC_6H_3(NO_2)_2 + H_2O$$

(5) The *peroxy group* is determined by treatment with sodium iodide. The liberated iodine is then titrated with standard sodium thiosulfate solution. The reaction is

$$RCOO_2OCR + 2\ NaI \longrightarrow I_2 + 2\ R'COONa$$

(6) The *primary amino group* is determined by treatment with nitrous acid and measurement of the nitrogen (gas) produced by the reaction

$$RNH_2 + HNO_2 \longrightarrow N_2 + ROH + H_2O$$

(7) The aromatic *nitro group* is determined by its reduction with excess titanium(III) chloride. After the reaction, the unused titanium(III) ions (Ti^{3+}) are determined by titration with iron(III) sulfate or iron alum solution:

$$RNO_2 + 6\ TiCl_3 + 6\ HCl \longrightarrow RNH_2 + 6\ TiCl_4 + 2\ H_2O$$

$$Ti^{3+} + Fe^{3+} \longrightarrow Ti^{4+} + Fe^{2+}$$

(8) The *hydrazino group* is determined by oxidation with copper(II) sulfate solution, and measurement of the nitrogen (gas) formed. The reaction is

$$RNHNH_2 + 4\ CuSO_4 + H_2O \longrightarrow N_2 + ROH + 2\ Cu_2SO_4 + H_2SO_4$$

(9) The *sulfhydryl group* is determined by reaction with iodine, which is produced in the vessel from potassium iodide, added in excess to the solution, and potassium iodate, added from a buret until the completion of the reaction is shown by the permanent appearance of the blue color of starch-iodine.

$$2\ RSH + I_2 \longrightarrow RSSR + 2\ HI$$

(10) *Unsaturated groups* are determined by addition of bromine, by the reaction

$$R_2C{=}CR'_2 + Br_2 \longrightarrow R_2CBr{-}CBrR'_2$$

The term *functional group analysis* sometimes is used to describe the foregoing kinds of analyses.

Ultimate Analysis. This term, generally limited to organic chemical analysis, denotes the determination of the proportion of each element in a given substance. The primary determination is that of carbon and hydrogen, which is conducted by mixing the sample with copper(II) oxide and heating it in a stream of oxygen to a temperature of 700 to 800 °C. The carbon is converted to carbon dioxide and the hydrogen to water. These products are then absorbed by suitable reagents. For example, magnesium perchlorate dehydrate may be used to absorb water and sodium hydroxide to absorb carbon dioxide. Although the fundamental procedure is simple, a rather elaborate train of apparatus, involving both temperature and flow control, is required. The traditional procedure for determining nitrogen is the Kjeldahl method. The Unterzaucher method is used for determining oxygen in organic substances, the sample is heated to a high temperature (approximately 1120 °C) in an atmosphere of nitrogen. Under these conditions, the oxygen present combines with part of the carbon content to form carbon dioxide and with part of the hydrogen content to form water. The gases then are passed over hot carbon (1150 °C), whereupon both the carbon dioxide and water are converted to carbon monoxide. The latter gas upon leaving the furnace is passed over iodine pentoxide I_2O_5 at about 110 °C to form iodine by the reaction: $5CO + I_2O_5 \rightarrow I_2 + 5CO_2$. The freed iodine is titrated with a standard sodium thiosulfate solution.

ANALYTIC CONTINUATION. Calculation of an analytic function over some domain, from precise definition of the function over a smaller domain.

Suppose $f_1(z)$ is analytic in D_1 and $f_2(z)$ in D_2 and that D has a region in common with both D_1 and D_2. Further suppose that $f_1(z) = f_2(z)$ in D, then if $f(z)$ can be defined so that $f(z) = f_1(z)$ in D_1 and $f(z) = f_2(z)$ in D_2 the analytic continuation of either $f_1(z)$ or $f_2(z)$ in the domain $(D_1 + D_2)$ is $f(z)$. As a simple example consider the series $(1/a + z/a^2 + z^2/a^3 + \cdots)$ which represents the function $1/(a - z)$ only within C_1, a circle of radius $|a|$. Another power series of the type $[1/(a - b) + (z - b)/(a - b)^2 + (z - b)^2/(a - b)^3 + \cdots]$, however, represents the same function outside C_1 if b/a is not real and positive. This series converges at points inside another circle that has regions in common with C_1. See also **Taylor Series**.

ANALYTIC FUNCTION. A function $f(z)$ of the complex variable $z = x + iy$ is analytic at a point on the z-plane if the function and its first derivative are finite and single-valued there. If this property applies to all points within a given region of the complex plane, $f(z)$ is an analytic function throughout the region. Any point at which the derivative fails to exist is a singularity or a singular point of the function. According to the Liouville theorem, if $f(z)$ has no singularity for z finite or infinite it is a constant.

Equivalent definitions of an analytic function are: (1) it must satisfy the Cauchy-Riemann equations and Laplace's equation; (2) it is analytic only if it may be represented by a convergent power series in some neighborhood of the given point.

Other words often used in place of analytic, and essentially equivalent, are holomorphic, meromorphic, monogenic, uniform, regular.

An analytic function of a real variable may be defined in a similar way. See also **Cauchy Theorem**.

ANALYZER (Optics). A term applied to the Nicol prism (or other device that passes only plane polarized light) which is placed in the eyepiece of a polariscope or similar instrument.

ANALYZER (Reaction-Product). Chemical composition may be determined by the measurement of a reaction product — in an automatic fashion utilizing the basic principles of conventional qualitative and quantitative chemical analysis. Two steps usually are involved in this type of instrumental analysis: (1) the formation of a target chemical reaction, and (2) the determination of one or more of the reaction products.

Determination of a constituent in a process stream or sample by measurement of a reaction product can be represented by: C + R → P, where C = constituent to be determined; R = reactant; and P = reaction product to be measured. If reactant R already is present in the sample, it is only required to expose the sample to suitable reaction conditions to form P. Under normal instrument operating conditions, the reaction of C and R may be spontaneous. In other instances, suitable conditions may have to be established either (1) to promote the desired reaction (for example, setting the proper temperature and pressure, or using a catalyst) or (2) to assure a suitable reaction rate.

Frequently, it is possible to measure the reaction product as it forms in the reaction zone. In some instances, the products and sample residue must be removed from the reaction zone before a measurement can be made. Also, the reaction product may be measured directly; or its presence may have to be inferred from a secondary reaction. In one example, carbon monoxide in air or oxygen may be determined by combustion to carbon dioxide. The latter may be measured directly as by thermal-conductivity methods; or inferentially by absorbing the carbon dioxide in a solution and then measuring the change of that solution by electrolytic conductance.

ANALYZER (Reagent-Tape). The key to chemical analysis by this method is a tape (paper or fabric) that has been impregnated with a chemical substance that reacts with the unknown to form a reaction product on the tape which has some special characteristic, e.g., color, increased or decreased opacity, change in electrical conductance, or increased or lessened fluorescence. Small pieces of paper treated with lead acetate, for example, have been used manually by chemists for many years to determine the presence of hydrogen sulfide in a solution or in the atmosphere. This basic concept forms the foundation for a number of sophisticated instruments that may pretreat a sample gas, pass it over a cyclically advanced tape, and, for example, photo-metrically sense the color of the exposed tape, to establish a relationship between color and gas concentration. Depending upon the type of reaction involved, the tape may be wet or dry and it may be advanced continuously or periodically. Obviously, there are many possible variations within the framework of this general concept.

ANAMNIA. Vertebrates that do not develop an amnion during embryonic life.

ANAMORPHISM. A term proposed by Van Hise in 1904 to designate the deep-seated constructive processes of metamorphism by which new complex (metamorphic) minerals are formed from the preexisting simpler minerals, as contrasted with the surface alteration of rocks due to weathering and cementation, termed katamorphism.

ANAPHYLAXIS. State of supersensitivity that may develop after a first injection of a foreign protein, such as a therapeutic or prophylactic serum. See also **Alkaloids**.

ANAPLASMOSIS. Anaplasmosis is a tick-borne disease of cattle and other ruminants, such as deer in the western United States and elk in the former USSR. It is caused by the protozoan *Anaplasma marginale*, so named because the organism appears to be devoid of cytoplasm and resides at the margin within an erythrocyte. At least 30 species of ticks have been shown to be capable of transmitting anaplasmosis under laboratory conditions. Horseflies are also vectors of the disease. Anaplasmosis is mild in young calves and increases in severity, being frequently fatal to cattle above the age of three. Although the disease may be asymptomatic, it is sometimes manifest by anorexia, weakness, fever, anemia, jaundice, reduced milk production, depression, dehydration, difficult respiration, and abortion. Infection can also cause infertility in bulls. The disease in its acute form occurs frequently in purebred animals and high producing milk cows, which may die in a few hours after the start of infection.

Imidocarb **(1)** dihydrochloride [CAS: 5318-76-3], the most effective drug against anaplasmosis, is reported to be curative in a single dosage if given early in the infection during the rise in parasitemia. Multiple doses are required if the animals are treated at a later stage or if a relapse occurs (Table 1). Some antibiotics active against the disease include the tetracyclines chlortetracycline (**2**, Aureomycin [CAS: 57-62-5]) and oxytetracycline [CAS: 79-57-2], which are now given in long-acting pharmaceutical dosage forms because of the need for extended treatment. Many other drugs, including arsenicals, antimonials, antimalarials, eg, chloroquine [CAS: 50-63-5] and amodiaquine **(3)**, the dihydrochloride dihydrate Camoquin [CAS: 6398-98-7]), and dyes have been employed in the past in an effort to cure or prevent anaplasmosis. α-Ethoxyethylglyoxal dithiosemicarbazone (Gloxazone) has a marked inhibitory effect on *A. marginale* but was found to be too toxic to lactating cattle.

ANA-POSITION. The position of two substituent groups on atoms diagonally opposite, in α-positions on symmetrical fused rings, as the 1,5 or the 4,8 positions (which are identical) of the naphthalene ring.

ANASTIGMAT. A compound lens combination corrected so that both astigmatism and the curvature of the field are largely eliminated over a considerable area in the image plane.

ANATASE. The mineral anatase, TiO_2 crystallizing in the tetragonal system is a relatively uncommon mineral. It occurs as a tri-morphous form of TiO_2 with rutile and brookite. Rutile and anatase have tetragonal crystallization; brookite, orthorhombic. Hardness, 5.5–6; sp. gr. 3.82–3.97; brittle with sub-conchoidal fracture; color, shades of brown, into deep blue to black; also colorless, grayish, and greenish; also transparent to opaque with adamantine luster.

Anatase occurs as an accessory mineral in igneous and metamorphic rocks, gneisses, and schists. Fine crystals have been found in Arkansas in the United States, and in Switzerland.

ANATEXIS. A term proposed by Sederholm in 1907 for the supposed end-process of deep-seated metamorphism resulting in the partial or complete re-melting of a specific type of rock in situ.

ANATOMY. A branch of biology dealing with structure, generally considered to be gross structure, but sometimes used to refer to microscopic structure as well. A subdivision of the more inclusive term, morphology, which includes all forms of study of structure. Human anatomy is a study

TABLE 1. ANAPLASMOSIS ANTIPROTOZOAL AGENTS[A]

of the various organs of the human body and their relationship to each other as to shape and position.

Classically, anatomy has been divided into a number of subclasses: (1) *gross anatomy*, which is a study of macroscopic structure, that is, the structure which can be seen with the unaided eye; (2) *comparative anatomy*, which studies the structures of animals in relation to each other, including human structure; (3) *developmental anatomy*, which studies both embryonic and later development of body structures; (4) *functional anatomy*, which studies the interaction of organs, particularly as they change in shape, size, pressure, temperature, and other important ways; (5) *microscopic anatomy* (histology), which investigates minute structure, particularly of cells in tissues and how cells develop into organs; and (6) *pathological anatomy*, which studies diseased structures, that is, the deviation from normal structures and functions. There also are the classical subclasses of *human anatomy*, *animal anatomy*, and *plant anatomy*.

Anatomists have likened the human body (and other vertebrates) to a tube that may be referred to as the *body wall*; this tube enclosing another tube referred to as the *viscera*. The cavity between the tubes may be referred to as the *body cavity* or *celom*. The principal cavities of the human body are outlined in Fig. 1. The major systems of the body are: (1) the *circulatory* or *vascular system* (blood, blood vessels, heart, lymphatic vessels and lymph); (2) the *digestive system* (alimentary canal, pancreas, liver, salivary gland; (3) the *endocrine system* (adrenals, parathyroids, pituitary, thyroid, portions of ovaries and testes, and other glands with ducts); (4) the *excretory system* (bladder, kidneys, ureters, urethra, respiratory systems of the skin); (5) *muscular system*; (6) *nervous system* (brain, ganglia, nerve fibers, spinal cord); (7) *reproductive system* (bulbo-urethral and prostate glands, penis, seminal vesicles, testes, and urethra in the male; ovaries, uterine tubes, vagina, and vulva in the female);

Abdominal Cavity	Nasal Cavity
Gallbladder	Structures forming the nose
Intestines	Orbital Cavities
Kidneys	Eyes, eyeball muscles
Liver	Lacrimal apparatus
Pancreas	Optic nerves
Pelvic Cavity	Peritoneal Cavity
Bladder	Pleural Cavities
Pelvis	Spinal Canal
Rectum	Spinal Cord
Spleen	Thoracic Cavity
Stomach	Blood and lymph vessels
Buccal Cavity	Esophagus
Teeth	Heart
Tongue	Lungs
Cranial Cavity	Trachea
Brain	Thymus gland

Fig. 1. Principal cavities of the body, indicating what they contain.

(8) the *respiratory system* (bronchi, larynx, lungs, nose, pharynx); and (9) the *skeletal system* (bones and connective tissue).

Needless to say, the dividing line between anatomy, physiology, and other biological and medical sciences is indistinct and growing less distinct as scientists emphasize the interdisciplinary approach to their work.

ANCHOR ICE. Ice attached to the beds of streams, lakes, and shallow seas, irrespective of its nature of formation. On clear, cold nights in relatively still water, anchor ice may form directly on submerged objects. It also develops in supercooled water if turbulence is sufficient to maintain uniform temperature at all depths, in which case a spongy mass of frazil accumulates on objects exposed to rapid flow, and later deposition fills in the pores and creates solid ice. When the water temperature increases to above 0 °C (32 °F), the ice rises to the surface, often carrying with it the object on which it had accumulated. Sometimes anchor ice is erroneously called ground ice, a term which should be reserved for bodies of more or less clear ice in frozen ground.

AMS

ANCHOR RING (or Torus). A surface that has the shape of a doughnut. It can be generated as a surface of revolution by rotating the circle.

$$(y - b)^2 + z^2 = a^2$$

around the Z-axis. Its equation, when rationalized, is of the fourth degree

$$(x^2 + y^2 + z^2 + b^2 - a^2)^2 = 4b^2(x^2 + y^2)$$

With dimensions as shown in Fig. 1, its volume, $V = 2\pi^2 Rr^2$ and its surface area, $A = 4\pi^2 Rr$.

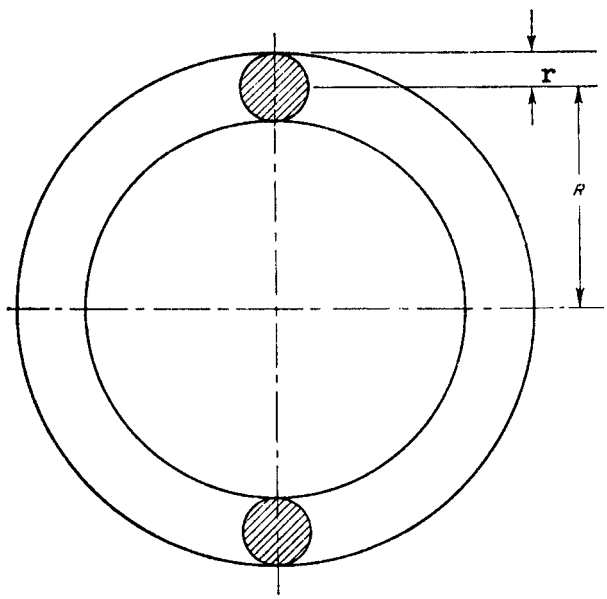

Fig. 1. Anchor ring.

This surface is of interest in topology, where it is said to be of genus 1.

See also **Circle (Geometry)**; and **Topology**.

ANCHOVY AND ANCHOVETA *(Osteichthyes).* The anchovy family (*Engraulidae*) comprises 15 genera and some 100 species. These fishes are found in the tropical and temperate regions of the northern and southern hemispheres. Distribution is chiefly in the Indian and Pacific Oceans. Anchovies school along the coast and some are also found in fresh water. Because of the great masses in which they occur, the family has large commercial importance to several countries for the production of fish meal and oil. One of the main differences between the anchovy and the herring is the prominent protruding upper jaw as indicated in Fig. 1.

Fig. 1. Striped anchovy (*Anchoa hepsetus*.)

Anchovies. Seven species in the main genus *Engraulis* have been identified from the Pacific and Atlantic Oceans. Included is the anchovy (*Engraulis encrasicholus*), which reaches about 8 inches (20 centimeters) in length, but is usually from 4.7 to 6.3 inches (12 to 16 centimeters) in length. Coloration resembles that of the herring, with silver lateral stripes. Distribution is chiefly in the Mediterranean Sea and Black Sea as well as on the Atlantic coast of southwest Europe and north Africa. In the north, the distribution extends to the English Channel, and to the south along the African west coast from Togo to Dahomey. Anchovies are also found in the Sea of Asov, in the southern North Sea, and in small numbers as far North as Bergen, Norway.

In their chief distribution region, e.g., in the Mediterranean, anchovies migrate little. In spring and summer, they appear in great schools at the surface of the water both in the open sea and along the coast. They spawn in the Mediterranean from April to September. During this time, they are also fished. After spawning, at the commencement of winter, the adults and the sub-adults from the spring and summer spawn move into depths of 329 to 492 feet (100 to 150 meters). The schools probably break up at this time and the fish remain in some small region at the floor of the sea. This is evident from studies made of their stomach contents.

Anchovies in the bordering regions of their distribution are migratory. They migrate from wintering grounds in the Black Sea in early spring to the Sea of Asov, where they spawn and return to the Black Sea in the fall. In northern regions, anchovies also migrate in great schools to the north and northeast. They move through the Bristol Channel into the Irish Sea and to the west coast of Scotland, where they can be found from May to September. Spawning grounds are presumably located in this area, since specimens found there are mature for spawning.

In spring, the anchovies migrate in great numbers through the English Channel to the North Sea. They move along the French-Belgian-Dutch coast to the East Frisian coast. The spawning grounds were located here in 1929, and considerable fishing activity developed there, particularly in the Zuider Zee. Since that time, particularly after World War II, it was observed in the southeastern North Sea that the number of anchovies decreased and that they also spawned there. Eggs and larvae were found as far as the North Frisian islands. The spawning period was in warmer brackish water from June to August. Climatic changes probably acted as a factor in the spread of anchovies to the north, as was the case with sardines. In the fall, the anchovies migrate through the northern part of the English Channel, along the English coast to wintering grounds off the west exit of the Channel.

The number of eggs varies between 13,000 and 20,000; they are laid in open water in groups. After a year, the fish are 3.5 to 4 inches (9 to 10 centimeters) long and spawn for the first time in the following summer at a length of about 4.75 and 5 inches (12 to 13 centimeters). The Sea of Asov anchovies, the smallest variety, grow at a slower rate. Anchovies feed on small plankton, chiefly on crustaceans of various families. Fish eggs have also been found in their stomachs. The anchovies are prey to many predatory fishes and marine birds.

The chief countries fishing anchovies include Russia, Spain, Italy, Turkey, the Balkan Countries, Greece, France, and Portugal. Anchovies are caught with drift-nets, baskets, ring-nets, and trawl nets. They are usually marketed in the salted form, in which the head and insides are removed. After an aging period of 4 to 18 months, during which time the flavor improves, the anchovies are ready for market. Part of the catch is worked into filets and conserved in oil. Anchovies are also used in the preparation of pastes and sauces.

Anchovetas. Anchovy fishing is also carried on in other parts of the world, as in the northern Pacific Ocean, on the coast of South Africa, and off Australia. The greatest fishing intensity on a single anchovy species has been carried on since the early 1950s off the coast of Peru and Chile. This species is *Engraulis ringens*, known as *anchoveta* in Spanish. The fish reaches a length of about 5.5 inches (14 centimeters). This is the most important fish in the diet of giant flocks of cormorants, pelicans, gannets, and other marine birds, which breed by the millions on the islands off western South America. The dung of these birds forms the basis of the guano industry. The anchoveta is also eaten by many other animals, including sea lions, dolphins, and predatory fishes.

As of the early 1980s, one of the world's largest fish meal and oil industries was based on these anchovetas. The anchovetas live in the Peruvian Current, ranging from central Chile (37°04′S) all along the Peruvian coast to Cabo Blanco (04°15′S) in a belt close to the shore and extending 30 miles (56 kilometers) out during the summer and 120 miles (222 kilometers) during the winter. The anchovetas spawn in both winter and summer, but with much more intensity and duration during the summer. They reach sexual maturity when approximately 1 year old when they are about 4.7 inches (12 centimeters) long. They can produce about 9000 eggs during several spawnings in the same season. It has been indicated that *E. ringens* spawns from 94°15′S to the south, and that the young anchovetas reach 3.1 and 3.5 inches (8 to 9 centimeters) in length at an age of about 6 months, being then recruited to the fishery. The diet of the species consists of 1% zooplankton and 99% phytoplankton.

The principal fishing gear is the purse-seine net. Most of the catch is reduced to fish meal and oil. Since guano is formed from anchovetas, the proper management of the anchoveta resource is of concern on 2 counts-the fish and the guano. The maximum sustainable catch of anchovetas from fishing and by birds has been estimated at about 10 million tons per year. It has been estimated that the catch by birds approximates 2.5 million tons per year. The Peruvian government has engaged in restricting the anchoveta catch to preserve a satisfactory balance between these two important resources.

Systematic studies of fish larvae have revealed that, with the decline of sardine population, its very close competitor, the anchovy has increased in abundance. It has been estimated by scientists of the California Cooperative Fishery Investigation organization that there exists off California and Baja California a standing stock of some 4 million tons of anchovies, enough to sustain a harvest of perhaps a million tons per year or more. It is believed that some reduction of the anchovy population might, at the same time, accelerate recovery of the heavily depleted sardine population.

ANCILLARY STATISTIC. In cases where no sufficient statistic exists, it is sometimes possible to find a set of statistics which provide no information on the parameter concerned, but which together with a suitable estimator exhaust all the information in the sample. Such statistics are called ancillary statistics; they provide information, not on the parameter, but on the accuracy with which it is estimated.

ANDALUSITE. An aluminum silicate corresponding to the formula Al_2SiO_5, and is one of a three-member polymorphous group consisting of andalusite, sillimanite, and kyanite. Andalusite occurs in contact-metamorphic shales, and in rocks of regional metamorphic origin in association with sillimanite and kyanite. Andalusite crystallizes in the orthorhombic system, developing coarse prisms of approximately square cross section, but may be massive or granular. It shows a distinct cleavage parallel to the prism; hardness 6.5–7.5; sp. gr., 3.13–3.16; vitreous luster; colorless to white, gray, brown, greenish, or reddish; streak, white; transparent to opaque.

This mineral is named for its original locality, Andalusia, Spain. A variety of andalusite, chiastolite, has carbonaceous impurities so oriented that they produce a cross or a tesselated figure at right angles to the prism. Chiastolite comes from the Greek word meaning a cross. Localities are the Urals, the Alps, the Tyrol, the Pyrenees, Australia, and Brazil; in the United States, at Standish, Maine; Sterling and Lancaster, Massachusetts; Delaware County, Pennsylvania; and Madera County, California.

When clear it is used as a gemstone, and it has also been used to manufacture porcelain for spark plugs.

AND (Circuit). A computer logical decision element that provides an output if and only if all the input functions are satisfied. A three-variable AND element is shown in Fig. 1. The function F is a binary 1 if, and only if, A and B and C are all 1's. When any of the input functions is 0, the output function is 0. This may be represented in Boolean algebra by $F = A \cdot B \cdot C$, or $F = ABC$. Diode and transistor-circuit schematics for the two-variable AND function are shown in Fig. 2. In modern integrated circuits, the function of the two transistors or diodes may be fabricated as a single active device. In the diode AND circuit, output F is positive only when both inputs A and B are positive. If one or both inputs are negative, one or both diodes will be forward-biased and the output will be negative. The transistor AND circuit operates in a similar manner, i.e., if an input is negative, the associated transistor will be conducting and the output will be negative.

Generally referred to as "fan in," the maximum number of input functions for which a given circuit configuration is capable is determined

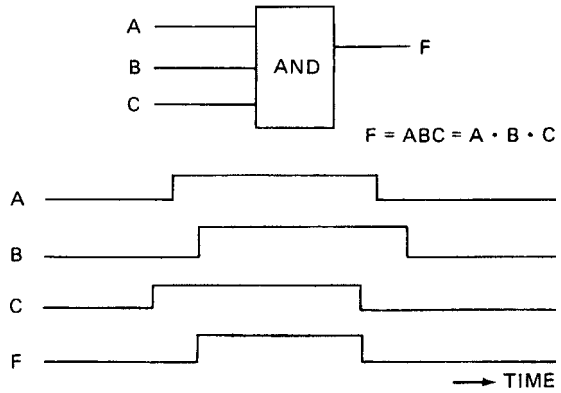

Fig. 1. AND circuit.

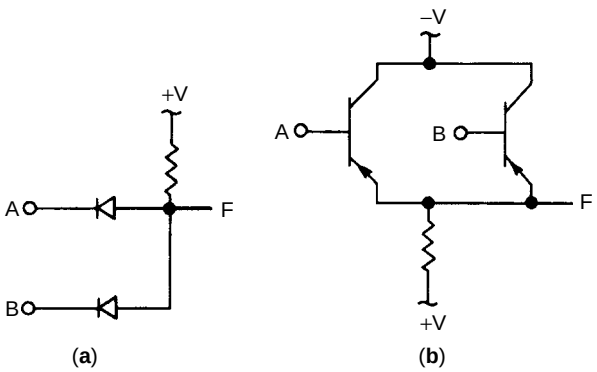

Fig. 2. **(a)** Diode-type AND circuit; **(b)** transistor-type AND circuit.

by the leakage current of the active element. Termed "fan out," the number of circuits which can be driven by the output is a function of current that can be supplied by the AND circuit.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

ANDESITE. A term originally applied to a porphyritic lava from the Andes Mountains by Leopold Van Buch. In modern terminology andesite is an extrusive igneous rock, the surface equivalent of diorite. In other words, it is composed chiefly of plagioclase, corresponding in chemical composition to oligoclase or andesine together, with biotite, hornblende, or pyroxene in varying quantities.

Andesites are of rather widespread occurrence, being found in the Rocky Mountains, California. Alaska, South America, and in many other localities.

ANDRADITE. Calcium-iron garnet.

ANDROGENESIS. The development of an egg after the entry of the male germ cell without the participation of the egg nucleus.

ANDROGENS. The relation between the testis and the male secondary sex characteristics has long been known. The evidence that a chemical substance present in the testis could elicit androgenic effects was not achieved until 1908 by Walker, who prepared an aqueous glycerol extract of bull testis tissue that caused growth of the capon's comb. More active extracts from bull testes were prepared in 1927 by McGee and Koch by using organic solvents. The extracts were assayed quantitatively by measuring the increase in area of the capon's comb. The discovery of androgenic activity in urine made possible the isolation of the first biologically active crystalline androgens by Butenandt et al. in 1931–1934. Androsterone and dehydroisoandrosterone were isolated from male urine. In 1935, David et al. isolated a crystalline hormone from bull testis extract. This possessed a higher biological activity than either androsterone or dehydroisoandrosterone. It was named testosterone. Testosterone was also prepared from cholesterol within months of its isolation from testular extract. See Fig. 1.

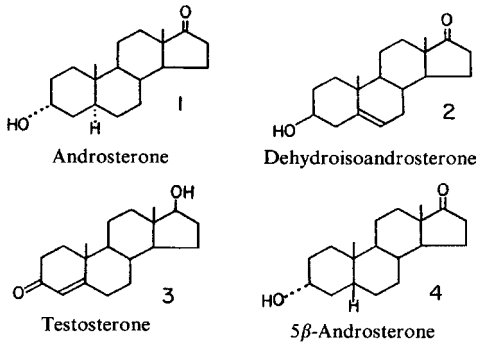

Fig. 1. Androsterone and related hormones.

As pointed out by Liddle and Melmon (1974), adrenal androgen production also carried out in the *zona fasciculata* and in the *zona reticularis*, varies greatly at different stages of life. The fetus makes significant amounts of adrenal androgen, whereas the child makes very little. Beginning with puberty, adrenal androgen production increases, reaches a peak in early adulthood, and then declines to rather low levels beyond age 50. On the other hand, the secretion of ACTH, the only known control of adrenal androgen biosynthesis, shows no age-related fluctuations. The full regulation of adrenal androgen production is not understood. Adrenal androgens are relatively weak, but some serve as precursors for hepatic conversion to testosterone. Hyperfunction of this pathway in the female may lead to significant masculinization. See also **Adrenal Glands**.

The androgens stimulate the development of the male secondary structures, such as the penis, scrotum, seminal vesicles, prostate gland, vas deferens and epididymis. The deepening of the voice, the growth of pubic, axillary, body, and facial hair, as well as the development of the characteristic musculature of the human male, are also under the influence of testosterone. If the testes fail to develop or are removed prior to puberty, these changes do not occur. Thus, testosterone is essential for reproductive function of the male.

The adrenal cortex produces hydroisoandrosterone, which is largely found in blood and urine conjugated as the sulfate ester. The amounts of androgen secreted by the normal adrenal cortex are insufficient to maintain reproductive function in the male. The normal human ovary and placenta also produce small amounts of androgenic steroids that serve as precursors for the estrogens in these tissues. In the human, little testosterone is excreted into the urine and virtually none into the feces. The principal metabolic transformation products are androsterone and 5β-androsterone, with small amounts of other reduced compounds. These substances are excreted in the urine in the form of esters with sulfuric acid or glycosides with glucuronic acid.

Like all other classes of steroid hormones, the androgens are synthesized from acetyl coenzyme A *via* mevalonic acid, isopentenyl pyrophosphate, farnesyl pyrophosphate, squalene, lanosterol, and cholesterol. Enzyme systems in the testis then catalyze the cleavage of the side chain of cholesterol to pregnenolone which can give rise to testosterone by the two pathways shown in Fig. 2.

Testosterone is formed by the interstitial or Leydig cells of the testes which develop under the influence of gonadotrophic hormones discharged into the bloodstream by the anterior pituitary gland. In pituitary insufficiency, this hormonal stimulus is lacking and, as a consequence, the Leydig cells do not secrete testosterone. In such instances, the male secondary sex characteristics fail to develop. However, interstitial cell tumors may occur, leading to excessive androgen production and precocious puberty. In women, tumors or excessive function of the adrenal cortex and, rarely, of the ovary, result in the production of large amounts of androgens with associated virilization.

Acne vulgaris, a chronic skin disorder, is related to androgen production. The post-pubescent development of the sebaceous glands and the onset of acne are dependent upon the presence of androgens, but are not related to testosterone blood levels. Sansone et al. (1971) observed that the hypothesis of increased end-organ sensitivity, which is supported by the heightened ability of skin with acne to metabolize testosterone, may explain the lack of correlation between levels of circulating androgens and occurrence and severity of the disease.

There is androgen involvement in polycystic ovary syndrome (PCO) and hyperthecosis. In 1935, Stein and Leventhal defined a condition with hirsutism, secondary amenorrhea, and enlarged ovaries — a syndrome now referred to as PCO. In this condition, the female usually shows signs of androgen excess, including increased body hair, but true virilism, with balding and deepening of the voice, is less common. Usually, one or both ovaries are enlarged. In many patients the ovaries are cystic, with thickened capsules, yet not palpably enlarged. It has been postulated that the development of PCO commences when luteinizing hormone (LH) triggers an increase in ovarian androgen, which is converted to estrogen, causing estrogen levels (particularly estrone) to increase. This is followed by an anterior pituitary response to luteinizing hormone-releasing hormone (LRH). This completes the cycle by creating exaggerated pulsatile but surgeless LH levels. The initiating lesion remains obscure. Wedge resection of one or both ovaries has largely been replaced by the administration of the antiestrogen clomiphene. This was the first drug known to trigger ovulation in women. Patients with anovulation arising from PCO are treated with the drug primarily when fertility is desired. The hirsutism found with PCO has been difficult to treat. Wood and Boronow (1976) reported that long intervals of anovulation, such as occur in PCO, may be a prelude to endometrial carcinoma. As postulated, the link may either be continuous exposure of the endometrium to estrogen unopposed by progesterone. There is also the postulation that estrone, the estrogen that appears to be high in this disorder, may be a causative factor. A carcinogenic role has been alleged for estrone.

In a somewhat related disorder, hyperthecosis, androgen excess tends to be greater. In this condition, there is prominent luteinization of the theca, whereas the cystic development and capsular thickening of the PCO are absent. Ovarian tumors making androgen can produce the features of PCO, but they tend to have a course with sharper onset and clearer progression.

Androgens also have been used in the management and treatment of agnogenic myeloid metaplasia, aplastic anemia, breast cancer, hereditary angiodema, osteoporosis, paroxysmal nocturnal hemoglobinuria, and sideroblastic anemia.

Oral androgens as may be used in hormone therapy for the management of metastatic breast cancer are effective in about 30% of women regardless of age, but virilizing doses of the hormone are usually required. The oral androgens carry the additional risk of toxic hepatitis.

Androgens may explain some of the differences between heart diseases of males and females. See **Heart and Circulatory System (Physiology)**.

ANDROMEDA. The brighter stars of this constellation make an almost straight line between the constellations of Perseus and Pegasus. The most famous feature of the constellation is the great spiral galaxy. This is the only spiral actually visible to the naked eye, and may be distinguished as a faint blur against a moonless sky close to the faintest star in the constellation. (See map accompanying entry on **Constellations**.) The distance of this spiral from the earth is about 1.84×10^6 light years.

The bright star in Andromeda closest on the map to Perseus was called Almach by the Arabs. It is a double star, and one of the most beautiful in the sky when viewed with a small telescope. One component is a brilliant orange and the other a striking emerald color. Careful examination with a large telescope shows the green component to be also a double star.

ANDROSTERONE. See **Steroids**.

ANELASTIC APPROXIMATION. See **Meteorology**.

ANEMIAS. The anemias comprise one of the major groups of diseases involving the blood and, in particular, the erythrocytes (red cells) and their hemoglobin, that is, the impairment of the blood's oxygen delivery system. Anemias may arise from (1) blood loss; (2) disorders of iron metabolism; (3) defects in erythrocyte production; and (4) hemolysis — destruction of erythrocytes.

A male weighing about 150 pounds (70 kilograms) will have just over 4 grams of iron in his body, with 61.7% in the form of hemoglobin; 3.5% (myoglobin); 0.2% (heme enzymes); and 34.6% in iron stores (transferrin, hemosiderin, ferritin). In a woman, there is a marked difference in the distribution of the iron. A female weighing about 132 pounds (60 kilograms) will have about 2.3 grams of iron in her body, with 81.4% in the form of hemoglobin; 5.4% (myoglobin); 0.3% (heme enzymes); and 12.9% in iron stores. The small quantity in iron stores is represented by blood loss in menstruation and in pregnancy and lactation.

Blood Loss and Iron Deficiency Anemia

Blood loss is classified as acute or chronic. In instances of blood loss from injuries, this may be immediately obvious to both patient and physician. Where there is massive acute blood loss, shock and death will occur if replacement therapy is not commenced in very short order. Where blood losses approximate one liter, there will be symptoms of incipient or overt shock. Symptoms will progress into shock, depending upon the severity of further losses. Also, in accidents, there may be deep tissue bleeding where blood losses may not be immediately apparent or measurable. For example, in the case of a fractured pelvis, where there is hemorrhage into the thigh and pelvic region, a liter or more of blood may be lost and not immediately detectable. In all severe cases of bleeding, infusions with colloid and electrolyte solutions will be commenced as soon as possible and before blood typing and cross-matching procedures can be completed. See **Blood**. Frequently, when available, a preparation known as *plasmanate* will be used. This preparation contains human plasma and a small quantity of albumin. Contrasted with dextran infusions, plasmanate does not cause platelet functional defects or red cells to aggregate. Concurrently, equal volumes of a saline-based electrolyte solution will be given. Once the

steps required to restore plasma volume and electrolytes have been taken, the physician will tackle the problem of replenishing the red blood cells.

Chronic blood loss is frequently attributed to gastrointestinal tract bleeding and, in women of child-bearing age, to blood losses from the genital tract. An average woman will lose from 30 to 60 milliliters of blood per month through menstruation. During pregnancy, there is division of iron from the mother to the fetus. There are further losses during parturition and lactation. A mother may lose from 700 to 900 milligrams of iron in this way. All of these factors may be contributory to *iron deficiency anemia*. Other factors may include disturbances in the absorption of iron and deficiency of dietary iron. Less frequently, iron deficiency anemia will be a result of intravascular hemolysis resulting in iron loss through the urine (*hemoglobinuria* and *hemosiderinuria*); or even a result of loss of blood to the lungs in an uncommon condition known as idiopathic pulmonary hemosiderosis.

Iron replacement therapy involves the oral or intravenous (depending upon severity and patient reactions) administration of iron compounds (commonly ferrous sulfate). The therapy is usually commenced at low levels and gradually increased so that gastrointestinal symptoms may be avoided.

In determining iron replacement requirements, numerous factors must be considered. There is no single laboratory value that defines anemia. For example, a person may lose nearly a liter of blood and show signs of impending shock from a bleeding peptic ulcer, yet samples of peripheral blood may show normal hemoglobin. This occurs because dilution of the blood (to restore loss of volume) does not occur for about 72 hours. As guidelines, the following stages of iron deficiency are used by some specialists in the field: *normal*, a hemoglobin level of 13–15 grams per 100 milliliters; *iron deficiency without anemia*, same values; *iron deficiency with mild anemia*, a hemoglobin level of 9–10 grams per 100 milliliters; *severe iron deficiency with severe anemia*, a hemoglobin level of 6–7 grams per 100 milliliters.

Anemias from Red Blood Cell Production Disorders (Erythropoiesis)

Although anemia may result from defects in red blood cell production alone, frequently one of these disorders will be accompanied by other factors (hemolysis or blood loss) which exacerbate the anemia. Sometimes, there are also associated depression of platelet and white blood cell counts.

As mentioned in entry on **Blood**, the erythrocytes are produced in bone marrow. In what is sometimes called the *anemia of chronic disorders*, the bone marrow appears to be normal. Examination will show that there is a normal ratio of myeloid cells (precursors of the erythroid cells) in the marrow and of the erythroid cells produced. This is classified as a mild anemia and is usually presented by patients who have chronic inflammatory, infectious, or neoplastic (presence of tumors) disease. Diagnosis of the underlying condition is often difficult. Anemia is frequently found in severe renal (kidney) disease. As described in the entry on **Blood**, a chemical messenger (*erythropoietin*) is released by the kidney to signal the rate of erythrocyte generation required. Dysfunction of this system can be a causative factor. Where renal disease is accompanied by chronic uremia (blood in urine) resulting from gastrointestinal bleeding, iron deficiency will add to the complications.

Also not directly marrow related are anemias resulting from starvation, such as anorexia nervosa or protein deficiency. These conditions may arise even though normal folate and vitamin B_{12} levels are maintained. Therapy is improvement of the diet. See **Anorexia**. Reduced red blood cell production not directly involving the marrow may also be caused by certain drugs, such as alcohol (which interferes with metabolism of folate and iron), chloramphenicol, and arsenic, among others, However, the latter drugs also can affect the marrow.

Aplastic Anemia. In this anemia, there is partial or nearly complete failure of the marrow to produce new red blood cells. This condition may arise from several causes, including ionizing irradiation, a number of chemotherapeutic drugs, as well as several diseases. There are also instances of idiopathic aplastic anemia which may be due to defective behavior of the stem cells. Benzene also has been implicated as a causative factor. Vigorous inhalation of some organic vapors (glue sniffing) can induce fatal aplastic anemia.

Among drugs that are frequently implicated in aplastic anemia are various *alkylating agents*, such as melphalan, cyclophosphamide, chlorambucil, and bisulfan; *antimetabolites*, including azathioprine, 6-mercaptopurine, 6-thioguanine, and methotrexate; and various *anti-tumor agents*, such as vinca alkaloids (vinblastine, vincristine), anthracyclines (daunorubicin, doxorubicin), among others. Drugs that occasionally cause aplastic anemia include arsenic, chloramphenicol, gold compounds, mesantoin, phenylbutazone, quinacrine, sulfonamides, and trimethadione. Diseases associated with aplastic anemia include viral hepatitis and paroxysmal nocturnal hemoglobinuria.

Biopsy may be required to determine aplasia of the marrow. In some cases, it may be found that the marrow has been replaced by tumors or fibrosis. Aplastic anemia has been treated with corticosteroids and splenectomy has been done, but their effectiveness has not been well documented. Aplastic anemia is a very serious disease and not always effectively treated, particularly if there are few if any surviving pluripotent stem cells. A marrow transplant may be considered. These are not always successful because of graft rejection, but the procedure may be the only remaining way of saving some patients' lives.

Megaloblastic Anemias. Commonly called *pernicious anemia*, this disorder is caused by vitamin B_{12} and folic acid deficiencies. In megaloblastic anemia, several features of the interactions between vitamin B_{12} and folic acid coenzymes are critical. See also **Folic Acid**; and **Vitamin B_{12} (Cobalamin)**. Because neither of these substances are produced by humans in adequate amounts, they must be absorbed from a good diet. Factors that cause vitamin B_{12} deficiency include: (1) inadequate diet, particularly resulting from strict vegetarianism; (2) inadequate absorption, such as from gastric abnormalities with deficient or defective intrinsic factor, small bowel disease, and pancreatic insufficiency; (3) interference with vitamin B_{12} absorption, as caused by fish tapeworm and certain drugs, such as neomycin, colchicine, para-aminosalicylic acid, and ethanol; and (4) rare congenital disorders, such as transcobalamin-II deficiency or defective intrinsic factor production. Factors which cause folic acid deficiency include: (1) inadequate intake, as in nutritional deficiencies and alcoholism; (2) relatively inadequate intake, as may occur during pregnancy, severe hemolysis, and chronic hemodialysis; (3) inadequate absorption, as occurs in tropical sprue, Crohn's disease, lymphoma or amyloidosis of small bowel, diabetic enteropathy, and intestinal resections or diversions; and (4) interference with folic acid metabolism, as may be precipitated by drugs blocking the action of dihydrofolate reductase (methotrexate, trimethoprim, and pyrimethamine), and by other drugs, the exact mechanisms of which are not known — phenytoin, ethanol, antituberculosis drugs, and possibly oral contraceptives.

Pernicious anemia usually does not occur before middle life. It results from the disappearance of the *intrinsic factor* and with it, hydrochloric acid from gastric juices. Upon progression of the disease, certain changes can occur in the spinal cord which result in weakness and numbness of the limbs and ultimately a full loss of ability to control them. Added to weakness and pallor, the symptoms may include loss of appetite, diarrhea, nausea, sore tongue, and yellow pigmentation of the skin. Until 1926, no treatment was known. In that year Minot and Murphy, American physicians, introduced the use of dietary liver as a specific treatment for patients suffering with pernicious anemia. For this work, they received the Nobel Prize in 1934.

Upon diagnosis of the disease, vitamin replacement therapy should be commenced immediately. Where the patient is symptomatic from severe anemia, packed red cells can be transferred very slowly to avoid precipitating or aggravating congestive heart failure. This will usually produce a 25% increase in oxygen-carrying capacity of the blood within a short period. Large, weekly doses of parenteral vitamin B_{12} are administered for several weeks, after which these may be scheduled on a monthly basis. Monthly doses may be required for the remainder of life. The physician will also encourage good dietary practice. Depending upon diagnosis, oral administration of folic acid may be indicated.

Sideroblastic Anemias. These comprise a heterogeneous group of disorders characterized by anemia and ineffective erythropoiesis.

Hemolytic Anemias

The anemias which result from increased red blood cell destruction are termed *hemolytic anemias*; they may be *normocytic* (red cells are of normal size) or *macrocytic* (red cells are larger than usual). Hemolysis may be caused by several differing conditions. In anemias caused by hemolysis, the breakdown of red cells releases large amounts of hemoglobin end products into the plasma. These substances are converted by the liver into a number of other pigments, most of which are excreted in the bile. If production of bile pigments is excessive, some appear in body tissues, giving rise to a

yellow appearance of the skin and the whites of the eyes. This condition is termed *jaundice* and is a symptom of the hemolytic anemias. The red cells are abnormally fragile and rupture easily in *hemolytic jaundice*. Thus, they are broken down by the spleen more rapidly than is usual. Such cells, without interference of the spleen, are able to function normally even though they are fragile. Thus, in some cases of hemolytic jaundice, the spleen is removed as a means of preventing too-rapid destruction of these cells. Some kinds of hemolytic anemia are inherited. Other types are acquired and may be associated with various systemic diseases. A number of drugs, physical and chemical agents, and vegetable and animal poisons have been suspect as causes. Corticosteroid therapy can be beneficial in some of these cases. Where there is no response to treatment, removal of the spleen is indicated.

Sickle Cell Anemia. This disease is caused by hemoglobin S that is inherited as a Mendelian dominant characteristic. It occurs as the *sickle trait* in 8–10% of black persons in the United States. In persons with sickle trait, the hemoglobin S concentration is less than 50% and, with rare exceptions, there are no symptoms. However, in *sickle cell anemia*, 70–98% of the hemoglobin is of the S type, leading to severe disease. The distribution of hemoglobin S in localities with a high incidence of malaria has suggested to some investigators that the sickle trait may provide some advantage to those who possess it. Studies have shown that persons with the sickle trait (but *not* with sickle cell anemia) are relatively resistant to the serious effects of falciparum malaria. It has been presumed that, in patients with the sickle trait, the parasitized cell "sickles" and thus is removed from the circulation in a sequence of events that breaks the parasite's life cycle. See **Malaria**.

Defective hemoglobin results in misshapen red cells and an inability of the blood to carry sufficient oxygen, thus producing anemia. Symptoms, as in the instances of other anemias, include general weakness and, in severe cases, headache, nausea, vomiting, fever, jaundice, and muscular and joint pains. The *sickle crisis*, which occurs in this disease, is a painful and dramatic expression of vascular occlusion. The initiating factor in the sickle crisis is not fully understood. Episodes of fever are known to predispose a patient to crisis. Studies in Ghana have shown that at the beginning of the malaria season, there are sharp increases in the incidence of sickle crisis. The traditional handling of the painful sickle crisis includes rest, the administration of drugs to relieve pain, and, if the patient is demonstrably acidotic, the administration of sodium bicarbonate in a 5% dextrose-water solution, normal saline solution, or half-normal saline solution. The bicarbonate solution is infused for a period of about 20 hours. During a crisis, the prevention of infection and other complications is very important. Past trials of oxygen therapy and urea therapy have not proved beneficial. Where a sickle crisis is of extreme severity, exchange transfusions may be indicated. As blood components are administered, part of the patient's blood will be drawn off. This procedure may be repeated three or more times, at the fastest rate permissible. Particularly in pregnant women, exchange transfusions are commenced at the beginning of the third trimester to avoid complications in pregnancy, which may include fetal death. Transfusions may be carried out at weekly intervals. Such a program also is sometimes used prior to surgery.

Persons with sickle cell anemia should be warned about the additional dangers of high altitude and dehydration. Genetic counseling to prospective parents is universally recommended among authorities.

During the 1980s, much research was directed toward a better understanding of sickle cell anemia and the development of improved methods of treatment and possible ultimate prevention.

In the references cited, Marx (1984) describes how parvovirus B19 causes a shutdown of red blood cell production in children with sickle cell anemia. Although this virus was discovered in human blood in 1975, it previously had not been associated directly with any specific disease. Marx (1985) reports of a new sickle cell test. This prenatal diagnostic test involves novel techniques for amplifying and analyzing specific DNA segments. Sickle cell anemia is a hereditary disease caused by the alteration of a single nucleotide in the beta-chain gene, which encodes one of the two proteins of the adult hemoglobin molecule. Individuals who inherit two copies of the mutant gene get sickle cell disease. Persons who inherit just one copy do not have the full-blown disease, but can pass the defective gene on to their children. Chien (1984) reports on microcirculation studies of sickle cell patients that provide insights to the rheological characteristics of sickle cells. In homozygous sickle-cell disease, deoxygenation of red cells causes the polymerization of hemoglobin S and transformation of the intracellular fluid into a viscoelastic gel. This process is most prominent in particularly dense red cells that have a high concentration of hemoglobin S. The membrane of these dense red cells also has elevated viscoelastic moduli, probably as a result of mechanical stresses exerted during sickle-unsickle cycles. Therefore, the densest cells are most rigid and have the greatest effect on resistance in blood flow through the microcirculation. Studies of the retina of patients with sickle-cell disease and the microcirculation of animals receiving human sickle-cell red cells have demonstrated that such red cells tend to be trapped at the entrance of narrow capillaries. Although only a small fraction of sickle-cell red cells have an abnormal rigidity at arterial oxygen saturation, their effects on microcirculatory flow may be magnified by their slow transit. Because the slowly moving rigid cells remain at the precapillary resistance sites for longer periods than cells with normal deformability, they may disproportionately occupy most of these sites, and exert a much greater effect on flow resistance than would be expected on the basis of their low percentage in the red-cell population.

Researchers in 1985, report on an interesting study of the types of sickle-cell anemia found in the black population of Africa, in which three different haplotypes were found in three different and specific geographical areas — the Senegal-type, the Benin-type, and the Bantu-type. It has been established for many years that black patients with sickle cell anemia in North America vary in the hematologic and clinical features of their disease. The variations generally can be attributed to the different geographical areas of origin on the African continent.

ANEMOMETER. This term refers to a general class of instruments designed to measure either total wind speed or the speed of one or more linear components of the wind vector. These instruments may be classified according to the transducer employed; those commonly used in meteorology include the cup, propeller, Pitot-tube, hot-wire or hot-film, and sonic anemometers. See also **Wind and Air Velocity Measurements**.

ANEMOMETRY. The measuring and recording of the force, speed, and direction of the wind, or an airflow, including its vertical component.

Systematic records of wind direction as indicated by wind vanes were begun in Italy in 1650 and in England in 1667. The speed of the wind was first observed by noting the rate at which light substances are carried along by the air; it is now determined by means of anemometers. See also **Anemometer**; and **Wind and Air Velocity Measurements**.

ANEMOTAXIS. Orientation of an insect to an air current as an in flight mechanism in seeking out a distant odor source. Some scientists now claim that insects also can follow an airborne odor trail in still air.

ANEROID. A thin, disk-shaped box or capsule, usually metallic, partially evacuated of air and sealed, which expands and contracts with changes in atmospheric or gaseous pressure.

The aneroid is the sensing and actuating element in various meters or gages, such as barometers, altimeters, manifold-pressure gages, etc; it is also the triggering or operating element in various automatic mechanisms. A device similar to an aneroid, but open to outside pressures, such as the capsule in an airspeed indicator, is not commonly called an aneroid.

ANEROID BAROGRAPH. (Sometimes called A*neroidograph*). An aneroid barometer arranged so that the deflection of the aneroid capsule actuates a pen that graphs a record on a rotating drum. The magnification of the deflection of the capsule may be adjusted so that records of small fluctuations in pressure may be obtained. The aneroid barograph is subject to the uncertainties of the aneroid barometer and therefore must be calibrated periodically. See also **Aneroid Barometer**; **Barograph**; and **Barometer**.

ANEROID BAROMETER. A type of instrument used for measuring atmospheric pressure. It is constructed on the following principles: An aneroid capsule (a thin corrugated hollow disk) is partially evacuated of gas and is restrained from collapsing by an external or internal spring; the deflection of the spring will be nearly proportional to the difference between the internal and external pressures; magnification of the spring deflection is obtained both by connecting capsules in series and by mechanical linkages. The aneroid barometer is temperature compensated at a given pressure level by adjustment of the residual gas in the aneroid or by a bimetallic link arrangement. The instrument is subject to uncertainties due to variations in the elastic properties of the spring and capsules, and due to wear in the mechanical linkages. See also **Barometer**.

ANESTHESIA (The History). Modern surgical anesthesia began in Boston, USA on 16 October 1846 when dentist William Thomas Greene Morton (1819–1868) administered diethyl ether to facilitate the removal of a tumor from the neck of Gilbert Abbot. Morton's feat, the first successful demonstration of chemically induced painless surgery, astonished and pleased those present, a collection of physicians and even a reporter. News of the event spread rapidly. Within weeks the first modern anesthetics had been given in Paris and London and within 6 months even in China and Australia, all of this in an age when most news still traveled by sailing ship.

Morton was not the first to attempt painless surgery. Throughout antiquity surgeons sometimes achieved a crude form of anesthesia by administering alcohol or by delivering a sharp blow to the head. During the eighteenth century they tried mesmerism, immersing appendages in freezing water prior to amputation, or applying constant pressure to a nerve until the limb "fell asleep." With the discovery of gases, early in the nineteenth century, several physicians began to explore their medicinal effects. Sir Humphry Davy, known for developing a safe miner's lamp, recognized that inhalation of nitrous oxide caused insensibility and he even suggested that it might be used for surgery. Henry Hill Hickman, another English scientist, made similar observations with carbon dioxide. Working in a small southern town, American physician Crawford Long performed surgery on a patient anaesthetized with ether: In 1844, American dentist Horace Wells successfully anesthetized patients with nitrous oxide. None of these events, however, succeeded in establishing the use of chemicals to achieve painless surgery. In some instances those involved failed to publicize their success, in others the demonstration failed at a crucial time. Until Morton, however, inhalation of ether or nitrous oxide remained a parlor sport or theatre stunt.

Morton built on the discoveries and work of others. He deserves credit, however, for recognizing the potential of ether-induced anesthesia, developing a reliable method for achieving it, and then picking an audience that could give his accomplishment credibility with the public and the medical profession. No less important, however, the times were right. During the preceding half century, chemistry and medicine had undergone spectacular change. It was an era that favored experimentation and discovery. In the wake of a series of political and social revolutions, the public developed confidence that anything might be achieved, including the control of disease and the abolition of pain. To many, Morton's demonstration in Boston represented an affirmation of their faith in progress and science.

A handful of physicians resisted the use of anesthesia for surgery, saying that they depended on the reaction of their patients to indicate whether they were excising healthy or diseased tissue. Most, however, accepted it and recognized that results improved when patients were anesthetized for surgery. Simultaneously, a handful of scientists and physicians began systematic studies of the pharmacology and physiology of anesthesia. Noted French physiologists François Magendie and Claude Bernard published important works. Russian surgeon Nikolai Pirogoff published a book containing extensive clinical observations as well as original scientific studies. Most impressive, however, was a series of papers and books by London physician John Snow. Snow conducted detailed studies of a variety of drugs. Such work, however, was exceptional. Most physicians simply used the drugs, sometimes even assigning their administration to nonmedical people. By trial and error, physicians found other drugs that had anesthetic properties. Most had unacceptable toxic properties and were soon discarded. Of these, only chloroform remained in use for any length of time.

The next important development was the discovery of the anesthetic properties of cocaine. In 1884, German ophthalmologist, Carl Koller discovered that he could operate without pain after instillation of a solution of this drug into the conjunctiva. Other physicians soon learned that they could achieve anesthesia of portions of the skin, a limb, or of the lower portion of the body by direct injection of cocaine into tissue, around a nerve or nerve plexus, or into the fluid surrounding the spinal cord — a form of anesthesia collectively described by the term "regional."

The development of chemistry and clinical pharmacology began to affect the clinical practice of anesthesia during the early years of the twentieth century. Virtually, all early anesthetics had been inhalation agents, chemicals that are liquids but which vaporize readily at room temperature. Although effective and relatively easy to administer even with crude equipments, all had drawbacks. Chief among these was the slow onset of action and long period required after surgery for dissipation of drug effects. Physicians soon learned that they could potentiate the desirable effects of inhalation agents, and counteract their undesirable effects, by simultaneous administration of other drugs. In 1875, for example, Pierre-Cyprien Oŕe demonstrated that he could administer chloral, a chemically synthesized drug, to achieve anesthesia by intravenous injection. This discovery had little practical effect on the practice of anesthesia, but it did pave the way for the introduction of barbiturates in 1903, a discovery of great importance. Intravenous barbiturates helped sedate patients prior to surgery and speed them through the "excitement" phase. Isolated from

opium by Sertürner a century earlier, physicians found that subcutaneous or intravenous administration of morphine improved the outcome. Discovery of the drugs and hormones that affect circulatory function, epinephrine and its congeners, for example, gave physicians the means to counteract some depressant effects of anesthetics on the circulatory system. Another important advance occurred with the clinical introduction of curare. Curare had been long used by South American hunters to paralyze prey; Canadian physicians H.R. Griffith and G.E. Johnson showed that curare could produce the muscle relaxation required for some surgical procedures, thereby obviating the need for deep, sometimes dangerous, levels of inhalation anesthesia. Increasingly, "an anesthetic" entailed the use of a combination of agents, each chosen to achieve a physical condition most appropriate for the particular operation being performed.

Developments in pharmacology further altered the clinical practice of anesthesia. Pharmacologists learned that subtle changes in drug structure, the substitution of certain ions or an alteration of chemical bonds, often produced major changes in drug potency, rapidity of onset, duration of action or toxicity. In many instances, pharmacologists not only developed a new drug, but also synthesized another compound to counteract the effects of the first. Techniques for administering drugs evolved as physicians relied more on intravenous rather than inhalation techniques. In some instances, use of an inhalation agent disappeared altogether. Increasing use of muscle relaxants necessitated better means of artificial ventilation. The extraordinary development of the electronics industry led to improvements in monitoring a patient's body functions during surgery.

Transducers facilitated the measurements of the electrocortical activity of the brain as well as of beat-to-beat electrical activity of the heart, fluctuations of blood pressure, breath-by-breath analysis of respiratory and anesthetic gas pressures in lung as well as comparable measurements in the blood. These, and other techniques, replaced simple measurement of pulse and blood pressure by palpation and sphygmomanometry that had been a routine part of clinical anesthesia for over a century.

The scope of anesthetic practice also evolved. Initially, the only goal had been to render patients unconscious, amnestic, pain-free and immobile during surgery. Gradually, however, good care included management of any bodily function deranged by the anesthetic or by the surgery itself. This included monitoring and regulating renal and pulmonary functions, metabolic processes, as well as fluid and salt balance.

Patients with underlying medical problems presented another challenge. Anesthesia practice soon included management of underlying medical disorders, for example, endocrine, cardiac and neurological problems, at least for the duration of the surgery. Later, with development of intensive care units, management of pulmonary, cardiac and pain status extended into the post-operative period.

Recently, anesthesia practice embraced the diagnosis and management of acute and chronic pain. In some instances this simply involved alleviation of pain from surgery or acute trauma. In other instances, however, anesthetists dealt with pain arising from cancer or other chronic medical problems. In this regard techniques of regional anesthesia, originally developed for surgery, proved invaluable.

Contributing to the development of anesthesia as a medical specialty was a growing awareness that good anesthesia is a prerequisite for successful surgery. In 1892, English physician J.F.W. Silk cited poor training of anesthetists as the reason for the undiminished rate of operative deaths. He suggested, and then developed, a course of study for all graduating medical students. S.O. Golden, in 1901, initiated similar changes in the United States. Shortly thereafter, a handful of American Medical Schools began to add trained anesthetists to their faculties. They initiated programs in research and developed close ties with basic scientists in physiology and pharmacology.

Coincident with the development of training programs, anesthetists began to develop professional societies. Among the first was the Society of Anesthetists formed in London in 1893 with a membership of 40. In 1912, A.F. Erdman and several colleagues founded the Long Island Society of Anesthetists, the organization that later became the New York Society of Anesthetists, which then became the American Society of Anesthesiologists; http://www.asahq.org/. These organizations, in turn, sponsored research journals and pressed for acceptance of anesthesia as a recognized medical specialty with its own examining board.

In most developed countries an anesthetic is either administered or directly supervised by a physician with four or more year's specialty training beyond medical school. At present, clinical training involves extensive experience with all types of surgery, familiarity with a wide range of medical problems, and a thorough study of physiology and the pharmacology of anesthetic drugs. Certification as specialist involves satisfactory completion of an accredited course of study, a minimum experience with different anesthetic techniques and surgical procedures, training in intensive care and pain management, satisfactory results from both a written and an oral examination and letters from certified specialists testifying to the applicant's ethical standards and clinical competence. ANESTHETICS. The term anesthesia comes from the Greek *anaisthai* or insensibility and constitutes a state in which perception of noxious events such as surgical procedures is imperceptible. This state may or may not be accompanied by loss of consciousness. A complete or general anesthetic given by the inhalation or intravenous routes produces hypnosis (profound sleep), analgesia, muscle relaxation, and protection against the increase in blood pressure and heart rate resulting from surgical stress (maintains homeostasis). An anesthetic which blocks the neural transmission of painful stimuli through afferent nerves and does not affect the level of consciousness can be classified as a local anesthetic.

The induction of general anesthesia produces a progressive deepening of the anesthetic state and represents, in the anatomical sense, a descending desensitization of the central nervous system (CNS). A progression of clinical signs are useful for estimating the depth of anesthesia. These signs vary somewhat for each anesthetic, but in general, four stages can be defined:

1. State of altered consciousness and analgesia indicative of action on cerebral canticle areas begin;
2. Loss of consciousness, often accompanied by delirium and excitement, occurs. Irregular respiration and motor movement result from depression of higher motor inhibitory centers with the release of lower motor mechanisms;
3. Stage of surgical anesthesia is reached in which spinal cord and spinal reflexes are abolished, providing relaxation of skeletal musculature. Within the four planes in this state are loss of corneal, conjunctival, pharyngeal, and laryngeal reflexes as the depth of anesthesia progresses;
4. Onset of respiratory paralysis occurs resulting from significant depression of the medullary respiratory center. Subsequent cardiovascular collapse ensues.

Most signs, which require a skeletal muscle reflex would not be apparent after treatment with a neuromuscular blocking drug or would be altered significantly by preoperative drugs. In these cases central nervous system monitoring via an electroencephalogram (EEG), and hemodynamic and blood gas monitoring, help assess the depth of anesthesia. The potency of

inhaled agents is expressed as the minimum alveolar concentration (MAC) that is required to prevent spontaneous movement in response to a surgical or equivalent stimulus in 50% of patients.

The onset of action is fast (within 60 seconds) for the intravenous anesthetic agents and somewhat slower for inhalation and local anesthetics. The induction time for inhalation agents is a function of the equilibrium established between the alveolar concentration relative to the inspired concentration of the gas. Onset of anesthesia can be enhanced by increasing the inspired concentration to approximately twice the desired alveolar concentration, then reducing the concentration once induction is achieved. The onset of local anesthetic action is influenced by the site, route, dosage (volume and concentration), and pH at the injection site.

Theories of General Anesthesia

Although the modern practice of anesthesia is exceedingly sophisticated, identification of the basic molecular mechanism underlying it is still lacking. Even whether the target sites of the inhalational anesthetics are lipid or protein remains unknown, although it is likely that proteins are intimately involved. The inhalational anesthetics are very diverse chemically, and extrapolation from the effect of a particular agent to the physiological state of anesthesia is problematic. However, anesthesia theories may be roughly divided into two categories: lipid theories and protein theories.

Although there are many varieties of the lipid theory all postulate that inhalational anesthetics exert their primary effects by dissolving in the lipid portions of nerves, thereby altering the conductivity. This theory is based on observations made at the turn of the twentieth century on the relationship between anesthetic potency and the partition coefficient of the agent between olive oil and gas [Meyer and Overton Refs]. The anesthetic potency of a wide variety of anesthetics, covering four orders of magnitude, correlates exceedingly well with the agent's oil-gas partition coefficient.

The primary site of action is postulated to be the lipid matrix of cell membranes. The lipid properties which are said to be altered vary from theory to theory and include: enhancing membrane fluidity; volume expansion; melting of gel phases; increasing membrane thickness, surface tension, and lateral surface pressure; and encouraging the formation of polar dislocations [Koblin and Miller Refs]. Most theories postulate that changes in the lipids influence the activities of crucial membrane proteins such as ion channels. The lipid theories suffer from an important drawback: at clinically used concentrations, the effects of inhalational anesthetics on lipid bilayers are very small and essentially undetectable [Franks and Lieb].

The direct interaction of inhalation anesthetics and proteins has been proposed as the cause of anesthesia. An inhalation agent, whether a noble gas or a fluorinated ether, could dissolve asymmetrically in a protein. Resultant conformational changes in the protein, if these changes occur, could then cause changes in biological activity, for example, the chloride ion channel which is modulated by many of the intravenous agents. Quantitative data on the binding of anesthetics to proteins are limited but are related to anesthetic partition coefficients. Although binding to a soluble protein and modulation of its function are not necessarily coupled, the proteins of interest are those involved in nerve impulse transmission and are embedded in lipid membranes. Thus dissociation of lipid and protein effects is not possible.

The membrane enzyme luciferase, responsible for light emission in fireflies, is sensitive to anesthetics, and the concentrations of inhalational agents which inhibit luciferase are the same as those which cause general anesthesia. Studies of various classes of inhalational agents and luciferase demonstrated that above a certain chain length in a homologous series, a point is reached where higher members are not anesthetic. The same cut-off effect in efficacy is observed in anesthesia. This effect is not explainable by lipid theory.

Anesthetic Agents

Inhalation Agents. An ideal inhalation anesthetic would exhibit physical, chemical, and pharmacological properties allowing safe usage in a variety of surgical interventions. The agent should be odorless, nonflammable at concentrations which are likely to be used in the operating room, and stable both on storage and to soda lime, which is used as the CO_2 absorber in the anesthetic circuit. Induction of, and recovery from, anesthesia should be rapid, and minimal side effects should be observed on the cardiovascular (depression and epinephrine compatibility) or central nervous systems (EEG activation). See also **Neuroregulators**. The drug should not be metabolized.

A number of inhalation anesthetics have been introduced to clinical practice. All agents introduced after 1950, except ethyl vinyl ether, contain fluorine. Agents such as ether, chloroform, trichloroethylene (Trilene), cyclopropane, and fluoroxene (Fluoromar), which were once used, have been displaced by the newer fluorinated anesthetics.

Historical Inhalation Agents. Diethyl ether produces excellent surgical anesthesia, but it is flammable. See also **Ethers**. Chloroform is a nonflammable, sweet smelling, colorless liquid which provides analgesia at nonanesthetic doses and can provide potent anesthesia at 1%. See also **Chlorinated Organics**. However, a metabolite causes hepatic cell necrosis. Trilene, a nonflammable colorless liquid, has a slower onset and recovery and a higher toxicity and chemical reactivity than desirable. Cyclopropane is a colorless gas which has rapid induction (2–3 min) and recovery characteristics and analgesia is obtained in the range of 3–5% with adequate skeletal muscle relaxation. See also **Hydrocarbons**. The use of cyclopropane has ceased, however, because of its flammability and marked predisposition to cause arrhythmias.

Because of the flammable nature of diethyl ether and cyclopropane, a number of hybrid molecules were prepared in an attempt to improve on the useful characteristics of each, but none were marketed. Structure activity relationships for halogenated hydrocarbons and ethers indicated that fluorine was the most suitable halogen to use in order to decrease the potential for cardiac arrhythmias. See also **Fluorine**. In addition, the introduction of fluorine decreases flammability and boiling point and increases stability. It also decreases anesthetic potency. Fluoroxene, 2,2,2-trifluoroethyl vinyl ether the first fluorinated ether prepared and commercialized, has oil/gas and blood/gas partition coefficients lower than ether, chloroform, or Trilene, contributing to a rapid onset and recovery. This agent is less potent (MAC = 3.4%) than other fluorinated hydrocarbons introduced later and its flammability is close to MAC. Whereas the agent is stable to soda lime, it is readily oxidized and hydrolyzed to trifluoroethanol and acetaldehyde and is unstable to light. Fluoroxene is also metabolized to a significant extent. Thus it is no longer used.

Intravenous Anesthetic. The intravenous (iv) anesthetic agents are of two types: those which are used to induce, but not maintain, anesthesia, and those which are useful not only for induction, but also for maintenance. The period of induction is perhaps the most crucial part of the anesthesia. The need is for an anesthetic agent having an extremely fast rate of onset and limited side effects. Fast onset minimizes the stress and agitation which could arise during a more lengthy induction. Various classes of compounds have been used. Among these are: barbiturates, opioids, steroids, benzodiazepines, and hindered phenols. But the ideal agent for both induction and maintenance has not yet been found. For this reason, balanced anesthesia is often used: a potent opioid is combined with an inhalation agent.

A major difference between the inhalational agents and the iv anesthetics is that the former probably exert their biological activity through physical effects while the latter, in most cases, function through a biological receptor-mediated pathway.

At the end of a surgery, when the decision is made to reverse opioid-induced activity, the primary concern is to eliminate the respiratory depressant effects inherent in the potent opiates used as anesthetics. This reversal, brought about by opioid reversal agents, can also diminish the analgesic effects of the opiates. There are two types of reversal agents: pure antagonists and mixed agonist–antagonists. The antagonists naloxone and naltrexone are the most commonly used, although the use of the agonist–antagonist nalbuphine is increasing because it maintains a moderate level of analgesia while reversing the side effects. Nalmefene, a long-acting reversal agent, is in clinical trials.

Local Anesthetics. Nerve impulses are initiated by membrane depolarization, effected by the opening of a sodium-ion channel and an influx of sodium ions. Local anesthetics act by inhibiting the channel's opening; they bind to a receptor located in the channel's interior. The degree of blockage on an isolated nerve depends not only on the amount of drug, but also on the rate of nerve stimulation.

Local anesthetic activity is usually demonstrated by compounds which possess both an aromatic and an amine moiety separated by a lipophilic hydrocarbon chain and a polar group. In the clinically useful agents (Table 1) the polar group is an ester or an amide. Activity may be maintained, however, when the polar function is an ether, thioether, ketone, or thioester.

TABLE 1. CLINICALLY USED LOCAL ANESTHETIC AGENTS

Agent	Method of application	Comment
	Amino esters	
Procaine	Infiltration, spinal	Slow onset, short duration
Chloroprocaine	Peripheral nerve and obstetric extradural	Fast onset, short duration, low systemic toxicity
Tetracaine	Spinal	Slow onset, long duration, high systemic toxicity
	Amino amides	
Lidocaine	Infiltration, iv regional, peripheral nerve block, extradural block, spinal and topical	Fast onset, moderate duration, low systemic toxicity, most versatile agent
Mepivacaine	Infiltration, peripheral nerve block, extradural	Similar to lidocaine
Prilocaine	Similar to lidocaine	Safest amino amide, methemoglobinemia at high doses
Bupivacaine	Infiltration, peripheral nerve block, extradural	Moderate onset, long duration, potential for cardiovascular side effects, sensory/motor separation
Etidocaine	Infiltration, peripheral nerve block, extradural	Fast onset, long duration, profound motor block

The profile of the ideal local anesthetic agent depends largely on the type and length of the surgical procedure for which it is applied. Procedures could include neuraxial (spinal and epidural) anesthesia, nerve and plexus blocks, or field blocks (local infiltration). In general, the ideal agent should have a short onset of anesthesia and be useful for multiple indications such as infiltration, nerve blocks, intravenous, extradural, spinal, and topical administration. The therapeutic indexes for systemic CNS and cardiovascular toxicity should be high and the agent should be compatible with the vasoconstrictor epinephrine.

ANESTRUS. A period in which there is lack of heat (estrus) in the female animal, thus precluding breeding during that period. The periods of sexual non-interest in the female that normally occur between regular heat periods generally are not referred to as anestrus. Rather, *anestrus* applies to those factors that break up the normal cycles of heat. For example, there is lactational anestrus, which is a period following the birth of the young; or there is seasonal anestrus, which is a perfectly natural condition with some animals. For example, in some regions, seasonal anestrus occurs in sheep during late-spring and early-to-midsummer months. Abnormal anestrus is always of concern to cattle, sheep, and swine producers because of the reduction in production of calves, piglets, and lambs during any given period.

ANEURYSM. A sac or pouch filled with blood that protrudes from the wall of an artery, a vein, or the heart. In a *true* aneurysm, the wall of the sac consists of at least one of the layers of tissue that make up the wall of the blood vessel. *False* aneurysms exist when all of the layers of the artery have ruptured, but the blood is still retained by the surrounding tissues. Occasionally, an artery and vein may be connected in such a manner that a continuing flow of blood passes from the artery to the vein. Such arteriovenous communications result from wounds, aneurysms, or congenital connections between the vessels.

Aneurysms may occur in any artery. The most common site is the large artery leading from the heart (the aorta). Small aneurysms sometimes develop in blood vessels as the result of injuries. The rupture of even a small aneurysm in the brain, heart, or other vital organ can be fatal.

Presently, the most common cause of aortic aneurysm is atherosclerosis, known as hardening of the arteries. Also, an injury to an arterial wall can leave it so weakened that an aneurysm eventually may occur. Infected (mycotic) aneurysms result from destruction of arterial walls by infectious agents. Typical of diseases that may leave a weakened blood vessel are pneumonia, streptococcal infections, and gonorrhea. Now very rare, aneurysms of the aorta formerly were common as the result of previous syphilitic infection.

Although an aneurysm may exist at any site along the aorta, the most common aneurysms are in the abdominal aorta. Symptoms depend upon size of the sac and parts of the body upon which it exerts pressure. The sacs frequently become large, sometimes larger than an orange and can cause severe crowding of the chest or abdominal cavity. Bulging of the area of the collar bone can result when the aneurysm is near the top of the aorta. Sometimes aneurysms are painful, the pain usually located in the center of the chest, or may radiate into the arms. Difficulty in breathing (dyspnea) is another common symptom. This results from pressure on the windpipe or smaller air passages leading to the lungs. Aneurysms may cause headaches, abdominal distress, or swelling in various parts of the body. Many aneurysms are without symptoms, however, and may not be discovered except as the result of an x-ray examination for some other purpose. Angiography, in which contrast material is introduced into the blood vessels, followed by x-ray examination, is a valuable diagnostic aid.

Although many aneurysms remain small and never require treatment, generally they tend to become larger and may progress to rupture. The major treatment is complete surgical excision of the aneurysm with subsequent restoration of circulation with an implanted, pleated artificial graft. Where the artery is small, the graft may be a segment of vein from the patient. Risk of rupture and development of more hazardous problems rise with a delay in surgical procedure.

For smaller blood vessels that supply non-vital areas, aneurysms may be tied off so that blood no longer passes through the distended area. Other arteries assume the work of the vessel that is closed-off.

Most cerebral aneurysms occur in or near the circle of Willis: 30% of cases are found in the anterior communicating artery; 25% in the carotid artery; 25% in the posterior communicating artery; 2% in the basilar artery; and 2% in the vertebral artery. Several other sites are less frequently involved. See **Central and Peripheral Nervous System and The Brain**. Sometimes large aneurysms will produce focal neurological signs that lead to a correct diagnosis prior to rupture. These aneurysms may occur at any age, but middle-aged persons are most prone to them. See also **Cerebrovascular Diseases**.

ANFINSEN, CHRISTIAN B. (1916–1995). An American biochemist who won the Nobel Prize for chemistry in 1972 for his work on ribonuclease, especially concerning the connection between the amino acid sequence and the biologically active conformation. He shared the Nobel Prize with Stanford Moore and William H. Stein. His doctorate was granted from Harvard.

ANGEL. A radar echo caused by a physical phenomenon not discernible to the eye. Angels are usually coherent echoes, whose phase and amplitude at a given range remain relatively constant, and are sometimes of great signal strength (up to 40 decibels above the noise level). They have been ascribed to insects flying through the radar beam, but have also been observed under atmospheric conditions that indicate there must be other causes. Studies indicate that a fair proportion of angels are caused by strong temperature and/or moisture gradients such as might be found near the boundaries of bubbles of especially warm or moist air. They frequently occur in shallow layers at or near temperature inversions within the lowest portion of the atmosphere.

ANGELFISHES *(Osteichthyes).* Of the family *Pomacanthinae*, angelfishes have a powerful spine on the lower rear edge of the front gill cover; there is generally no axillary scale at the base of the pectoral fin. The spine distinguishes angelfishes from the closely related butterfly fishes (*Chaetodontinae*) which have no similar spine. Angelfishes are among the most beautiful of fishes and are usually found on tropical reefs. They tend to travel alone or in small groups. Although most angelfishes are much smaller, some reach a length of 2 feet (0.6 meter). These fishes are not only well known to the fishers in their native habitats, but have also become very popular in Europe and North America as aquarium fishes. Their image often is found on aquarium hobbyist organization emblems, since hobbyists have long been attracted to them. See Fig. 1.

The length of the angelfish *Pterophyllum scalare*, when fully developed in its natural habitat, may attain about 10 inches (25 centimeters). This fish inhabits the entire Amazon and its tributaries, resulting in the development of various geographic races differing in shape as well as coloration. Spawning usually occurs on a strong plant stem, or a large leaf. Both partners clean off the spawning surface beforehand. Both parents also care for the young together. Scalares do not build spawning pits to which the young are brought after hatching. Instead, the young fish are carried in the parents' mouth and suspended either directly on the spawning surface, or some other cleaned area. This is done with the help of fibers projecting from adhesive glands on the top of the heads of the young. Both parents guard the developing eggs and the hatched young.

Species of angelfish include:

Blue Angelfish (*Pomacanthus semicirculatus*), tropical Indo-Pacific.
Blue-faced Angelfish (*Pomacanthus xanthometopon*), tropical Indo-Australian region.
Imperial Angelfish (*Pomacanthus imperator*), tropical Indo-Pacific.
French Angelfish (*Pomacanthus arcuatus*), tropical Atlantic, from the Florida Keys to Brazil.
Potter's Angelfish (*Centropyge potteri*), Hawaiian Islands.

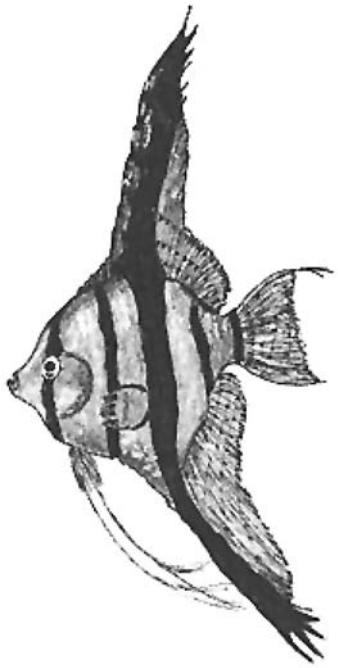

Fig. 1. Amazon angelfish (*Pterophyllum scalare*). (*Sketch by Glenn D. Considine*.)

Queen Angelfish (*Holacanthus ciliaris*), southwestern and northeastern Gulf of Mexico to Brazil.
Regal Angelfish (*Pygoplites diacanthus*), central Indo-Pacific (tropical).
Rock Beauty (*Holacanthus tricolor*), Florida to Brazil.

ANGEL SHARK *(Chondrichthyes).* The species *Squatina squatina* is the largest angel shark, with a maximum length of about 8 feet (2.5 meters) and weight of 160 pounds (73 kilograms). Angel sharks are intermediate between sharks and rays. Other species of the family *Squatinidae* are seldom longer than 4 to 5 feet (1.2 to 1.5 meters) at maturity. They prefer inshore waters, rarely frequenting deep waters. One exception is the Atlantic American *Squatina dumeril*, one specimen of which was found at a depth of some 4200 feet (1260 meters). Although angel sharks are not considered dangerous to swimmers, they are of a nasty disposition when out of the water and thus, if hooked, pose a danger to fishermen. They survive in captive waters for only a few weeks or months. The Pacific American *Squatina californica* inhabits waters from Alaska to lower California and like most angel sharks prefers temperate waters.

ANGINA. Angina is chest pain or discomfort that occurs when the heart muscle does not get enough blood. Angina may feel like pressure or a squeezing pain in the chest. The pain may also occur in the shoulders, arms, neck, jaw, or back. It may also feel like indigestion.

Angina is a symptom of coronary artery disease (CAD), the most common type of heart disease. CAD occurs when plaque builds up in the coronary arteries. This buildup of plaque is called atherosclerosis. As plaque builds up, the coronary arteries become narrow and stiff. Blood flow to the heart is reduced. This decreases the oxygen supply to the heart muscle. See also **Thrombosis**.

Types of Angina

The three types of angina are stable, unstable, and variant (Prinzmetal's). It is very important to know the differences among the types.

- **Stable Angina** Stable angina is the most common type. It occurs when the heart is working harder than usual.
  - There is a regular pattern to stable angina. After several episodes, one learns to recognize the pattern and can predict when it will occur.
  - The pain usually goes away in a few minutes after one rests or takes angina medicine.
  - Stable angina is not a heart attack, but makes it more likely that one will have a heart attack in the future.

- **Unstable Angina** Unstable angina is a very dangerous condition that requires emergency treatment. It is a sign that a heart attack could occur soon. Unlike stable angina, it does not follow a pattern. It can occur without physical exertion and is not relieved by rest or medicine.
- **Variant Angina** Variant angina is rare. It usually occurs at rest. The pain can be severe and usually occurs between midnight and early morning. It is relieved by medicine.

Not all chest pain or discomfort is angina. Chest pain or discomfort can be caused by a heart attack, lung problems (such as an infection or a blood clot), heartburn, or a panic attack.

What Causes Angina?

Angina is caused by reduced blood flow to an area of the heart. This is most often due to coronary artery disease (CAD). Sometimes, other types of heart disease or uncontrolled high blood pressure can cause angina.

In CAD, the coronary arteries that carry oxygen-rich blood to the heart muscle are narrowed due to the buildup of fatty deposits called plaque. This is called *atherosclerosis*. Some plaque is hard and stable and leads to narrowed and hardened arteries (Fig. 1). Other plaque is soft and is more likely to break open and cause blood clots. The buildup of plaque on the inner walls of the arteries can cause angina in two ways:

- By narrowing the artery to the point where the flow of blood is greatly reduced
- By forming blood clots that partially or totally block the artery

See also **Arteries and Veins**; and **Ischemic Heart Disease**.

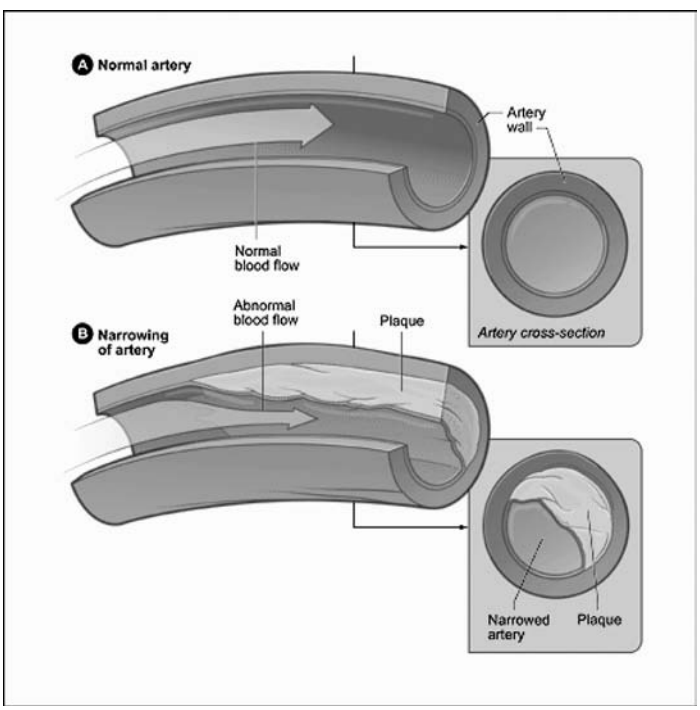

Fig. 1. The illustration shows a normal artery with normal blood flow (Figure A) and an artery containing plaque buildup (Figure B).

Angina Types

Stable Angina. Physical exertion is the most common cause of pain and discomfort from stable angina. Severely narrowed arteries may allow enough blood to reach the heart when the demand for oxygen is low (such as when you are sitting). But with exertion, like walking up a hill or climbing stairs, the heart works harder and needs more oxygen. Other causes include:

- Emotional stress
- Exposure to very hot or cold temperature
- Heavy meals
- Smoking

Unstable Angina. Unstable angina is caused by blood clots that partially or totally block an artery. If plaque in an artery ruptures or breaks open, blood clots may form. This creates a larger blockage. The clot may grow large enough to completely block the artery and cause a heart attack. Blood clots may form, partly dissolve, and later form again. Chest pain can occur each time a clot blocks an artery.

Variant Angina. Variant angina is caused by a spasm in a coronary artery. The spasm causes the walls of the artery to tighten. This narrows the artery, causing the blood flow to the heart to slow or stop. Variant angina may occur in people with and without CAD. Other causes of spasms in the arteries that supply the heart with blood are

- Exposure to cold
- Emotional stress
- Medications (vasoconstricting) that constrict or narrow blood vessels
- Cigarette smoking
- Cocaine use

Signs and Symptoms. Pain and discomfort are the main symptoms of angina. These symptoms

- Are often described as pressure, squeezing, burning, or tightness in the chest
- Usually start in the chest behind the breastbone
- May also occur in the arms, shoulders, neck, jaw, throat, or back
- May feel like indigestion

Some people say that angina discomfort is hard to describe or that they cannot tell exactly where the pain is coming from. Symptoms such as nausea, fatigue, shortness of breath, sweating, light-headedness, or weakness may also occur.

Symptoms vary based on the type of angina.

Stable Angina. The pain or discomfort:

- Occurs when the heart must work harder, usually during physical exertion
- Is expected, and episodes of pain tend to be alike
- Usually lasts a short time (5 minutes or less)
- Is relieved by rest or angina medicine
- May feel like gas or indigestion
- May feel like chest pain that spreads to the arms, back, or other areas

Unstable Angina. The pain or discomfort:

- Often occurs at rest, while sleeping at night, or with little physical exertion
- Is unexpected
- Is more severe and lasts longer (as long as 30 minutes) than episodes of stable angina
- Is usually not relieved with rest or angina medicine
- May get continuously worse
- May signal that a heart attack will happen soon

Variant Angina. The pain or discomfort:

- Usually occurs at rest and during the night or early morning hours
- Tends to be severe
- Is relieved by angina medicine

Diagnosis

Sometimes, your physician can diagnose angina by noting your symptoms and how they occur. You physician may order one or more tests to help make a diagnosis of angina. These tests are.

EKG (Electrocardiogram). This test measures the rate and regularity of your heartbeat. Some people with angina have a normal EKG.

Stress Test. Some heart problems are easier to diagnose when the heart is working harder and beating faster than when it is at rest. During stress testing, one exercises (or are given medicine if one is unable to exercise) to make the heart work harder and beat faster while heart tests are performed.

During exercise stress testing, your blood pressure and EKG readings are monitored while the patient walks or run on a treadmill or pedal a bicycle. Other heart tests, such as nuclear heart scanning or echocardiography, also can be done at the same time. These would be ordered if the doctor needs more information than the exercise stress test can provide about how well the heart is working.

If unable to exercise, a medicine can be injected through an intravenous line (IV) into the bloodstream to make the heart work harder and beat faster, as if one is exercising on a treadmill or bicycle. Nuclear heart scanning or echocardiography is then usually done.

During nuclear heart scanning, radioactive tracer is injected into the bloodstream, and a special camera shows the flow of blood through the heart and arteries. Echocardiography uses sound waves to show blood flow through the chambers and valves of the heart and to show the strength of the heart muscle.

A physician also may order two newer tests along with stress testing if more information is needed about how well your heart works. These new tests are magnetic resonance imaging (MRI) and positron emission tomography (PET) scanning of the heart. MRI shows detailed images of the structures and beating of your heart, which may help the doctor better assess if parts of the heart are weak or damaged. PET scanning shows the level of chemical activity in different areas of the heart. This can help the doctor determine if enough blood is flowing to the areas of the heart. A PET scan can show decreased blood flow caused by disease or damaged muscles that may not be detected by other scanning methods.

Chest X-Ray. A chest x ray takes a picture of the organs and structures inside the chest. These include heart, lungs, and blood vessels.

Nuclear Heart Scan. This test provides the doctor with moving pictures of the blood passing through the heart's chambers and arteries and shows the level of blood flood to the heart muscle. A small amount of a radioactive tracer is injected into your bloodstream through a vein, usually in the arm. A special camera is placed in front of the chest to show where the tracer lights up in healthy heart muscle and where it does not light up (in heart muscle that has been damaged or has a blocked artery).

There are different types of nuclear heart scans. Most scans have two phases — taking pictures of the heart at rest and while it is beating faster (called a *stress test*), although sometimes only a rest scan is done. Many heart problems show up more clearly when your heart is stressed than when it is at rest. By comparing the nuclear heart scan of the heart at rest to the heart at "stress," a physician can determine if the heart is functioning normally or not.

Echocardiogram. This test uses sound waves to create a moving picture of your heart. Echocardiogram provides information about the size and shape of the heart and how well the heart chambers and valves are functioning. The test also can identify areas of poor blood flow to the heart, areas of heart muscle that are not contracting normally, and previous injury to the heart muscle caused by poor blood flow.

There are several different types of echocardiograms, including a stress echocardiogram. During this test, an echocardiogram is done both before and after the heart is stressed either by exercise or by injecting a medicine into your bloodstream that makes the heart beat faster and work harder. A stress echocardiogram is usually done to find out if one has decreased blood flow to your heart (coronary artery disease).

Cardiac Catheterization. A thin flexible tube (catheter) is passed through an artery in the groin (upper leg) or arm to reach the coronary arteries. A doctor can determine pressure and blood flow in the heart's chambers, collect blood samples from the heart, and examine the arteries of the heart by X-Ray.

Coronary Angiography. This test is done during cardiac catheterization. A dye that can be seen by X-Ray is injected through the catheter into the coronary arteries. A physician can see the flow of blood through the heart and the location of blockages.

Blood Tests. 1). A fasting lipoprotein profile to check cholesterol levels. 2). Fasting glucose test to check blood sugar level. 3). C-reactive protein (CRP) test. This blood test measures CRP, a protein in the blood that shows the presence of inflammation. Inflammation is the body's response to injury. High levels of CRP may be a risk factor for CAD. 4). A test to check for low hemoglobin in the blood. Hemoglobin is the part of red blood cells that carries oxygen to all parts of the body.

Treatments

Treatment for angina includes lifestyle changes, medicine, special procedures, and cardiac rehabilitation. The main goals of treatment are to:

- Reduce the frequency and severity of symptoms
- Prevent or lower the risk of heart attack and death

Lifestyle changes and medicine may be the only treatments needed if your symptoms are mild and are not getting worse. Unstable angina is an emergency condition that requires treatment in the hospital.

Lifestyle Changes. The first thing that you need to do is change living habits to avoid bringing on an episode of angina.

- Slow down or take rest breaks, if angina comes on with exertion.
- Avoid large meals and rich foods that leaves one feeling stuffed, if angina comes on after a heavy meal.
- Try to avoid situations that makes one upset or stressed, if angina comes on with stress. Learn techniques to handle stress that cannot be avoided.

One can also make other lifestyle changes, for example:

- Eat a healthy diet to prevent or reduce high blood pressure, high blood cholesterol, and obesity
- Quit smoking
- Be physically active, as directed by a doctor
- Lose weight, if overweight or obese.
- Follow doctor's orders and take all medicines as directed, especially if diabetes is a factor also.

Medications. **Nitrates** are the most commonly used medicines to treat angina. Fast-acting preparations are taken when angina occurs or is expected to occur. Nitrates relax and widen blood vessels, allowing more blood to flow to the heart while reducing its workload.

One can use nitrates in different forms to:

- Relieve an episode that is occurring by using the medicine when the pain begins
- Prevent an episode from occurring by using the medicine just before pain or discomfort is expected to occur
- Reduce the number of episodes that occur by using the medicine regularly on a long-term basis

Nitroglycerin is the most commonly used nitrate for angina. Nitroglycerin that dissolves under your tongue or between your cheeks and gum is used to relieve an angina episode. Nitroglycerin in the form of pills and skin patches is used to prevent attacks of angina. These forms of nitroglycerin act too slowly to relieve pain during an angina attack.

Other medicines can be used to treat angina:

Beta blockers slow the heart rate and lower blood pressure. They can delay or prevent the onset of angina.

Calcium channel blockers relax blood vessels so that more blood flows to the heart, reducing pain from angina. Calcium channel blockers also lower blood pressure.

ACE (angiotensin-converting enzyme) inhibitors lower blood pressure and reduce the strain on the heart. They also reduce the risk of a future heart attack and heart failure.

People who have angina may also use: Medicines to lower cholesterol levels or to lower high blood pressure.

- Oral antiplatelet medicines (such as aspirin and clopidigrel), taken daily, to stop platelets from clumping together to form blood clots. Platelets are small blood cells that circulate through the blood vessels and help stop bleeding by sticking together to seal small cuts or breaks in tiny blood vessels. Antiplatelet medicines may not be appropriate for some people because they increase the risk of bleeding. Discuss the benefits and risks with a doctor before starting therapy with aspirin or the other antiplatelet medicines. See also **Platelets**.
- Glycoprotein IIb-IIIa inhibitors are potent antiplatelet medicines that prevent clots from forming in arteries. They are given intravenously in hospitals for the treatment of angina or during and after angioplasty.
- Anticoagulants to prevent clots from forming in arteries and blocking blood flow.

Special Procedures. When medicines and other treatments do not control angina, special (invasive) procedures may be needed. Two commonly used procedures are.

Angioplasty. This procedure opens blocked or narrowed coronary arteries. It can improve blood flow to the heart, relieve chest pain, and possibly prevent a heart attack. Sometimes a stent is placed in the artery to keep it propped open after the procedure.

Coronary Artery Bypass Surgery. This procedure uses arteries or veins from other areas in the body to bypass blocked coronary arteries. Bypass surgery improves blood flow to the heart, relieves chest pain, and can prevent a heart attack.

Prevention

One can prevent or lower your risk for heart disease and angina by making lifestyle changes and getting treatment for related conditions.

One can prevent or lower your risk for angina and heart disease by making healthy lifestyle choices (see **Lifestyle Changes**).

In addition to making lifestyle changes, one can help prevent angina and heart disease by treating related conditions, such as:

- High blood cholesterol. If one have high cholesterol, follow a doctor's advice about lowering it. Take medications to lower cholesterol as directed.
- High blood pressure. If one has high blood pressure, follow a doctor's advice about keeping blood pressure under control. Take blood pressure medications as directed.
- Diabetes (high blood sugar). If one has diabetes, follow a doctor's advice about keeping your blood sugar levels under control. Take medicines as directed.
- Overweight or obesity. If one is overweight or obese, talk to a doctor about how to lose weight safely.

ANGIOGRAPHY. In making an angiogram, a catheter is inserted into the individual's heart, a radiopaque medium is injected, and x-ray images and motion pictures may be made. These pictures indicate the locations where arteries are blocked and the degree to which the blockage has developed. Motion picture studies show details of heart function. Contrast angiograms are usually indicated when surgery or other therapy is being considered for persons with angina pectoris and those who are recovering from heart attack. In another version of this technique, the heart can be labeled with radioactive tracers which emit gamma rays. Images are made with a scintillation camera that is sensitive to gamma radiation. Through the use of computer techniques, three-dimensional x-ray or gamma-ray pictures of the heart can be created. Scintillation camera images have come into rather wide application as a means of diagnosing heart attacks, particularly where electrocardiograms may not be fully definitive, and where certain other clinical findings, such as serum enzymes, may not confirm heart damage. Technetium-99 m, a radionuclide tracer, has a particular affinity for recently damaged heart muscle. After intravenous injection, these tracers find their way to damaged areas and emit gamma rays which are picked up as bright areas in the scintillation camera image. In persons with unstable angina pectoris, where other clinical findings are indefinite, the radioactive tracers tend to collect in the heart. Another approach is to inject radioactive tracer consisting of a monovalent cation, such as potassium-43 or thallium-201. Upon intravenous injection of these materials, the substances lodge in the heart in proportion to blood flow. Portions of the heart that are deprived of blood flow thus appear as blank regions in the scintillation camera image.

In modern medicine, where useful information can be obtained by way of noninvasive techniques, the latter are preferred. Many advancements in noninvasive procedures were made during late 20th Century and, to some extent, these have affected invasive procedures, such as traditional angiography as just described. Noninvasive techniques are of particular preference in the early stages of diagnosis in the absence of an emergency situation. Such techniques include echocardiography and computed tomography (CT), nuclear magnetic resonance (NMR), and three dimensional (CT).

ANGIOMA. A tumor composed mainly of blood vessels (hemangioma) or of lymph vessels (lymphangioma). Both forms are ordinarily harmless: in the skin a hemangioma may appear as a disfiguring *naevus* or "port-wine stain"; lymphangiomas generally form soft bulky swellings especially about the neck.

ANGIOPLASTY. See **Coronary Thrombosis**.

ANGIOSPERMS. The angiosperms represent the most advanced division of the Pteropsida. They are more familiarly known as flowering plants, and the characteristic feature is the flower. The seeds are borne completely enclosed in the ovary tissue of the parent plant.

As a rule the angiosperms are land plants. A few of them have returned to the water as a habitat, but these are obviously reversions to an aqueous life. Tremendous diversity in size is found in this group; some of the so-called duckweeds are spherical masses of cells less than a millimeter in diameter; at the other end of the scale are the giant *Eucalyptus trees*, many of which are over 300 feet (90 meters) high. The variety of form shown in the angiosperms is nearly endless; each of the nearly 200,000 species has a distinct appearance. Some are tiny, herbaceous plants that live but a few weeks; others are giant trees living hundreds of years.

Included in the angiosperms are two types of plants. One, held to be the more primitive type, has a woody stem that has a much more complex structure than that found in the stems of gymnosperms. The other has an herbaceous stem, a form of stem which dies to the ground at the end of the growing season. The internal structure of angiosperm stems is much more specialized than that of gymnosperms. The xylem contains not only tracheids but also vessels and fibers. The vessels are open tubes of considerable length through which water is carried rapidly. The fibers give strength to the stem. In the phloem there are sieve tubes and companion cells, and also numerous fibers. In the woody angiosperms and in many of the herbaceous forms there is a well-developed cambium.

Reproduction in the angiosperms is described under **Flower**. Many of the angiosperms have highly developed mechanisms to ensure pollination and fertilization, and elaborate systems for the protection, dissemination, and germination of the seeds.

The angiosperms are separated into two large groups, the dicotyledons and the monocotyledons. The origin of the angiosperms is as yet unknown. They are known to have existed in the Jurassic period, but were not at all abundant until the Cretaceous period (see **Paleobotany**). The earliest fossil members of this group are well-differentiated plants, which give little indication as to their possible ancestry. Within the group, adaptation seems to be from the woody type to the herbaceous, and from plants with flowers having an indefinite number of parts arranged in spiral manner and not fused. As adaptation ensued, the number of flower parts became reduced and definite and finally fused. In many cases great irregularity replaced the more primitive regularity. The angiosperms are the dominant land flora of the present day.

ANGLE (Mathematics). The figure obtained by drawing two straight lines, called the sides of the angle, from a point, called the vertex. In trigonometry, an angle measures the rotation of one straight line, the terminal line, about a fixed point on an initial line. It is positive if the direction of rotation is counterclockwise. A unit for measuring angles is the radian, which is that angle whose intercepted arc in a circle equals the radius of the circle. Thus π radians $= 180^\circ$; 1 radian $= 180^\circ/\pi = 57.29578\cdots^\circ$ or $57^\circ 17' 44.6''$, approximately, and 1° is approximately 0.017453 radian.

If the magnitude of an angle equals 2π radians, it is called a perigon angle and such an angle, divided into 360 equal parts, has a magnitude of 360°. A right angle equals 90° or $\pi/2$ radians; a straight angle, 180° or π radians; an acute angle is less than 90°; an obtuse angle, greater than 90° (but frequently limited to one less than 180°). A reflex angle is greater than 180° but less than 360°. Oblique angle is a general term for one not equal to 90° or 180°. Related angles are designated as follows: conjugate, if their sum equals 360°; supplementary, if the sum equals 180°; complementary,

if 90°; vertical, if they have a vertex in common and the sides of one angle are prolongations of the sides of the other.

An angle inside a circle is central, if its sides are radii and its vertex is at the center of the circle; inscribed, if its sides are chords and its vertex is on the circumference of the circle.

The previous definitions refer to a plane angle, which is usually meant by the word angle, without a qualifying adjective. However, there are several other kinds of angles as the subsequent discussion will show.

The angle between two intersecting planes is called a dihedral angle. The line of intersection of the planes is the edge of the angle and the planes are the faces of the angle. Two dihedral angles are adjacent if they have a common edge and face. If two planes are parallel, the dihedral angle between them is zero; if perpendicular, the two adjacent angles are right dihedral angles. The plane angle of a dihedral angle is formed by two straight lines, one in each plane, perpendicular to the edge at the same point. The terms vertical, acute, obtuse, complementary, supplementary, etc., as used for plane angles, are also applied to dihedral angles.

Analytically, the dihedral angle can be defined as

$$\cos\theta = \lambda\lambda' + \mu\mu' + \nu\nu'$$

where the direction cosines of perpendiculars to the two intersecting planes are (λ, μ, ν) and (λ', μ', ν'). In vector notation, the relation becomes

$$\cos\theta = \csc\phi_2 \csc\phi_3(\mathbf{e}_{12} \times \mathbf{e}_{23}) \cdot (\mathbf{e}_{23} \times \mathbf{e}_{34})$$

where $\mathbf{e}_{ij}$ is a unit vector drawn from point i to point j; $\mathbf{e}_{23}$ is on the edge of the dihedral angle; $\mathbf{e}_{12}$ on one face and $\mathbf{e}_{34}$ on the other; ϕ_2 is the plane angle determined by the first vector product and ϕ_3 that angle determined by the second vector product.

If three or more planes meet at a common point, a polyhedral angle exists. The vertex, edges, faces, and face angles are defined as for plane and dihedral angles. The polyhedral angle is convex if every section made by a plane cutting all of its edges is a convex polygon. It is called trihedral, tetrahedral, etc., when it has three, four faces, etc. A trihedral angle is rectangular, birectangular, trirectangular, if it has one, two, or three right dihedral angles. If the vertex of a trihedral angle is at the center of a sphere, its faces intersect the sphere in great circle arcs and spherical angles are formed (see **Triangle**).

Now consider a small cone with a base of area dS and a vertex at a fixed point P. The cone will cut out an area $d\sigma$ on a sphere of radius r with center at P. The angle subtended by dS at P is defined as $d\omega = d\sigma/r^2$ and is called a solid angle. It is numerically equal to the area cut out by the same cone on a sphere of unit radius at the same point P. The unit used for measuring a solid angle is the steradian. Since the area of a sphere of unit radius equals 4π, the total solid angle about a point is 4π steradians.

ANGLE OF ARRIVAL. A measure of the direction of propagation of electromagnetic radiation upon arrival at a receiver (most commonly used in radio). It is the angle between the plane of the phase front and some plane of reference, usually the horizontal, at the receiving antenna. This angle is a function of the index of refraction gradient of the medium through which the energy is traveling, and the relative positions of the transmitter and receiver. Angles of arrival can be measured for both the direct and reflected components of a wave using a multiple-antenna receiving system called an *interferometer*.

ANGLE OF DEPARTURE. The angle between the line of propagation of a radiowave and the earth's surface at the point of transmission.

ANGLERFISHES *(Osteichthyes).* All members of the anglerfish order (*Lophiformes*) have a modified single movable dorsal fin ray which carries a kind of "bait" at its end; this is the basis of the name *anglerfish*. The "bait" is known technically as the illicium. Other unusual modifications in this group include the pectoral fins, which enable the fishes to crawl along the ground. All anglerfishes are slow-moving, almost motionless fishes, attracting their prey by means of their natural bait, at which time they suck in the prey with an extremely fast motion. The mouth acts as a giant suction trap.

Three suborders are distinguished: (1) *Goosefishes*, with 1 family; (2) *frogfishes*, with 4 families; and (3) *deepsea anglerfishes*, with 10 families. Altogether there are 225 species of anglerfishes distributed for the most part in tropical, subtropical, and temperate waters of the world's seas.

It is generally believed that anglerfishes developed from perch-like fishes that took on the frog-like shape as an adaptation to their life between rocks in coastal zones. According to this viewpoint, the modified pectoral fins act to ensure balance in the breaking waves. In further developments, the goosefishes adapted to living in deep coastal waters on the floor. The frogfishes adapted to living in dense plant growths, such as Sargassum seaweed; and the deep sea anglerfishes returned to a pelagic life, losing their dependence on a supporting object.

Goosefishes. These fishes are of suborder *Lophioidei*, family *Lophiidae*. They achieve a length exceeding 4 feet (1.2 meters) and a weight of about 45 pounds (20 kilograms), and are the largest anglerfishes. It has been reported that these fishes spend most of their lives lying on the bottom, where they blend into their surroundings so well that they can barely be perceived. Goosefishes are flattened from the back toward the belly (i.e., not laterally). The most striking part of the body is the head, the width of which is about two-thirds its length. The mouth opening extends over almost the entire width of the head; it has many needle-sharp teeth that seem capable of holding anything they grab. To attract prey, goosefishes use their bait, the illicium, which has been formed from the first six spiny rays of the dorsal fin. This consists of a line, at the end of which dangles a fleshy, sometimes worm-shaped shred of skin, which is literally dangled in the water by the goosefish. If another fish approaches with the mistaken idea that this is a worm, the goosefish waits motionless until the prey is close enough to catch. This method of predation must be extremely successful, because goosefishes that are caught almost always have their stomachs full, so full in fact that their contents sometimes equal one third of the body weight of the fish. The prey includes many species of fishes, crustaceans, cephalopods, and other organisms. When hungry, goosefishes gather in shallow water visited by diving birds, — because even small birds are eaten.

During the spawning period of the *allmouth* or *angler (Lophius piscatorius)*, which occurs in early summer along the European coasts and between January and February in the North Atlantic Ocean, the females develop a special kind of appetite. The fish leave their grounds near the coast and move into deeper regions (3280 and 6560 feet; 1000 and 2000 meters). The eggs are released in long, gland-secreted tubes up to 1 foot (30 centimeters) wide, $\frac{1}{4}$-inch (5 millimeters) thick and as long as 13 feet (4 meters). The eggs are situated singly or by twos in six-sided compartments in a sort of honeycomb arrangement. Eventually, the structure tears and the eggs float individually in the water until the young hatch. The larvae, which are about $\frac{1}{8}$-inch (2 millimeters) long, swimming near the surface of the water do not resemble their parents at all; they look much more like typical fish larvae. After a four-month larval period, with growth up to a length of 4 to 6 inches (10 to 15 centimeters), and a complex change in body shape, the juvenile goosefishes have the adult appearance and behavior.

In spite of their unusual appearance, goosefishes are popular as food. The head and leathery skin are removed so that little remaining in the frying pans looks like the original fish. In Europe, the fishes are sold fresh or smoked as "trout sturgeon."

Frogfishes. These fishes are of the suborder *Antennarioidei* and are usually small, seldom exceeding a length of 12 inches (30 centimeters). All frogfishes have a peculiar body shape, enabling them to resemble their surroundings to such a high degree that they blend into the algae "forests" like the Sargasso frogfish. This mimicry of surroundings is created by many skin folds and various skin formations, supplemented by the ability to adapt to some extent in color and pattern in the background. Frogfishes that do not swim well are prevented from falling through the Sargasso seaweed or other objects by their pectoral fins, which function much like human hands in grabbing and holding objects. The reproduction and other life habits of this suborder remain essentially unknown. Female frogfishes observed in aquariums have produced spawning tubes similar to those in goosefishes.

Deepsea Anglerfishes. These fishes are of the suborder *Ceratioidei* and are characterized by the absence of pectoral fins and the fact that only females have a fishing organ. While goosefishes and frogfishes live primarily in shallow water and may migrate into deeper water only for spawning, the approximately 120 species of deepsea anglerfishes are found at substantial oceanic depths, ranging from 985 to 13,125 feet (300 to 4000 meters). Any typical bait on the end of a fishing line would no longer be recognizable at these depths, so deep sea anglerfishes have a luminous organ at the end of the line. Production of the light is not fully understood,

but some authorities attribute this to the presence of luminous bacteria. See Fig. 1.

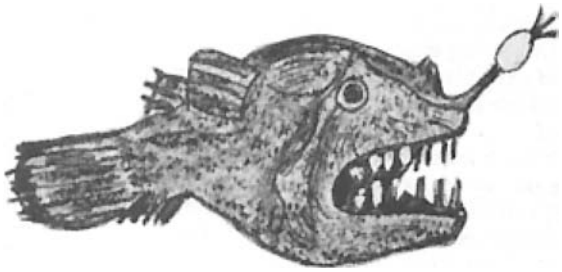

Fig. 1. Deepsea anglerfish. (*Linophryne arborifer*.)

Parasitic Males. The ceratiid anglers (*Ceratiidae*), photocorynid anglers (*Photocorynidae*), and linophrynid anglers (*Linophrynidae*) are species with very small males which parasitize the females and stay with them. The males do have their own gill respiratory system and the necessary vessels to supply their organs with oxygen, but their food is obtained from the bloodstream of their female hosts, with certain blood vessels in the males' heads in a dependent relationship with vessels in the females. Close examination of the dwarf males shows that several systems are more or less degenerated in them, particularly the teeth and the intestinal tract. They also lack the fishing line, as do all male deep sea anglerfishes.

The biological significance of parasitic males is related to the method of propagation of the species. Despite numerous signaling systems, including the luminous organs, it remains difficult for the different sexes to find each other in the deep sea, where all sunlight is absent. This dangerous disadvantage is offset by having just one partner seek food while the other parasitizes the food gatherer. Exemplary of the size differences is the female *Ceratias hollbolli*, which is some 40 inches (103 centimeters) long, as compared with the male, which averages about 3.5 inches (9 centimeters) in length. The size differences are not this large in some species.

The female deep sea anglerfishes are very active predators which feed on large organisms. Their jaws have powerful teeth and their stomachs are so greatly distensible that they can swallow prey that is larger than they are.

Deep sea anglerfishes primarily inhabit warmer parts of the Atlantic, Pacific, and Indian Oceans. Their numbers decrease sharply in the northern and southern temperate zones. Only a few species have been found in the north Atlantic Ocean.

Researchers, at the Department of Biology, California State University (Long Beach, California) studied the action of a species of Antennarius that originated in the Philippine waters. These investigators found that the pattern of movement of the illicial apparatus seems to be species-specific, ranging from simple strokes in the vertical plane to a complex triangular pattern, alternating with rapid sinusoidal thrusts. As reported by Pietsch and Grobecker (1978), "During a single luring sequence the illicium is initially brought straight forward in front of the mouth of the angler, and the bait is rapidly vibrated for 1 or 2 seconds. The bait is then held nearly motionless as the illicium is slowly laid back again onto the head and returned to its non-luring position. When the animal is sufficiently aroused, however, the bait makes a large and rapid sweeping motion that describes a nearly perfect circle. The thin membranous quality of the bait allows it to ripple while being pulled through the water, simulating the lateral undulations of a swimming fish. The lure thus provides not only a highly attractive visual cue but presumably also a low-frequency pressure stimulus for potential prey." Further details are given in *Science*, **201**, 369–370 (1978).

In 1979, researchers at the College of Fisheries, University of Washington (Seattle, Washington), made a high-speed photographic study of the feeding actions of antennariid anglerfishes. It was found that single feeding events for the anglerfishes occur at speeds greater than four times those described for other fishes. Further details are given in *Science*, **205**, 1161–1162 (1979).

ANGLESITE. Naturally occurring lead sulfate ($PbSO_4$), which crystallizes in the orthorhombic system and may be found mixed with galena, from which it is usually formed by oxidation. Hardness, 3; specific gravity, 6.12–6.39; luster, adamantine to vitreous or resinous; transparent to opaque; streak, white; colorless to white or green, but rarely may be yellow or blue. This mineral is used as a source of lead.

Anglesite, whose name derives from Anglesey, England, is found in many European localities; in the United States it has been found in large crystals in the Wheatley Mine, Phoenixville, Pennsylvania, and also in Missouri, Utah, Arizona, and Idaho.

ANGLE (Slip). 1. The angle included between the direction of the applied force and the surface of shear during the plastic flow of a solid body. 2. The angle of repose. See also **Repose (Angle of)**.

ANGLE-WING *(Insecta, Lepidoptera)*. Butterflies of the genus *Polygonia*. Their wings are sharply angular but no more so than those of some other species.

ANGOLA CURRENT. See **Ocean Currents**.

ÅNGSTROM (Å). A unit of length almost one non-hundred millionth (10^{-8}) centimeter. The Ångstrom is defined in terms of the wavelength of the red line of cadmium (6438.4696 Å). Used in stating distances between atoms, dimensions of molecules, wavelengths of short-wave radiation, etc.

ANGSTROM, ANDERS JONAS (1814–1874). Angstrom was a Swedish spectroscopist. Ångström was born in Lögdö, Medelpad, and educated at the University of Uppsala. After graduating, he taught physics there from 1839 until his death. He discovered the existence of hydrogen in the atmosphere of the sun. The angstrom, a unit of wavelength of light, is named in his honor.

See also **Units and Standards**.

J. M. I.

ÅNGSTROM COMPENSATION PYRHELIOMETER. An instrument developed by K. Ångström for the measurement of direct solar radiation. The radiation receiver station consists of two identical manganin strips whose temperatures are measured by attached thermocouples. One of the strips is shaded, whereas the other is exposed to sunlight. An electrical heating current is passed through the shaded strip so as to raise its temperature to that of the exposed strip. The electric power required to accomplish this is a measure of the solar radiation. See also **Actinometer**.

ÅNGSTROM PYRGEOMETER. An instrument developed by K. Ångström for measuring the effective terrestrial radiation. It consists of four manganin strips, of which two are blackened and two are polished. The blackened strips are allowed to radiate to the atmosphere while the polished strips are shielded. The electrical power required to equalize the temperature of the four strips is taken as a measure of the outgoing radiation.

ANGULAR DISTRIBUTION (Particle). In physics, the distribution in angle, relative to an experimentally specified direction, of the intensity of particles or photons resulting from a nuclear or an extranuclear process. Commonly, the specified direction is that of an incident beam, and the angular distribution is that of particles which are scattered or are the products of nuclear reactions. Alternatively, the specified direction might be that of an applied field, or a direction of polarization, or the direction of emission of an associated radiation.

ANGULAR MAGNIFICATION. The ratio of the tangent of the angle with the optical axis made by a ray upon emergence from an optical instrument to the tangent of the angle for the conjugate incident ray.

ANGULAR MEASUREMENT (Eccentricity Correction). A correction for eccentricity must be applied to many types of instruments used for astronomical angular measurement. Instruments for this purpose usually consist of a circle graduated in angular units, and an arm, assumed to be concentric with the circle, that sweeps around the circle, carrying a vernier, or a measuring microscope, for the purpose of determining accurately the direction of the arm relative to the circle. It is practically a mechanical impossibility to make the centers of the circle and the measuring arm exactly coincident.

In the Fig. 1, point C is the center of the circle OMA, graduated from O. C' is the center of the measuring arm (commonly known as the alidade). The direction $C'M$ is the actual direction of the alidade, and OM is the direction obtained from the circle reading (i.e., the angle OCM). The difference between these two directions, the angle $C'MC$, is the eccentricity correction for the circle reading OM. This will be different for different circle readings, being zero for the circle reading OA.

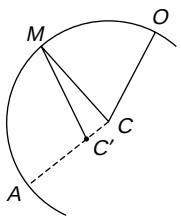

Fig. 1. Eccentricity correction for circle with alidade.

An equation may be developed that will give the eccentricity correction for any circle reading as a function of the reading and three numerical constants. To determine these constants, at least three known angles must be measured with the instrument. The differences between the values obtained with the instrument and the known values of the angles are the eccentricity corrections for the circle readings. These eccentricity corrections are then used for the solution of three equations for the three constants. With the constants determined, the equation, giving the eccentricity correction for any circle reading, may be written. The results are usually tabulated, or plotted on a curve and supplied by the maker of the instrument.

ANGULAR MOMENTUM (Particle). The vector product of the instantaneous values of the position vector and the linear momentum,

$$\mathbf{M} = m\mathbf{r} \times \mathbf{v}$$

For an interacting system of particles, the law of the conservation of angular momentum states that the rate of change of the total angular momentum equals the vector sum of the moments of the external forces applied to the system,

$$\frac{d}{dt}\sum_s M_s = \sum v_s \times F_s$$

where the summation is over the particles composing the system. In the absence of external forces, the angular momentum remains constant and no change of configuration can alter the total angular momentum of the system. Thus, a slowly rotating swarm of particles, like a cloud of gas in space, if it contracts under its own gravitational attraction, must rotate the more rapidly to keep its angular momentum constant. In the atmosphere, rotating airmasses tend to preserve their absolute angular momentum and the strong winds in hurricanes arise from the convergence of air into the lower levels.

If the particles are bound together in a rigid body, it is convenient to define the moment-of-inertia tensor

$$I_{ij} = \sum_s m_s(\delta_{ij} v_e v_e = v_i v_j)_s$$

where the position vectors are relative to the center of mass. Then the total angular momentum due to motion about the center of mass is

$$M_i = T_{ij}\omega_j$$

where ω_j is the instantaneous angular velocity of the rigid body (repeated tensor suffixes indicate summation).

The principle of conservation applies to angular as well as to linear momentum. That is, no change of configuration within a system, uninfluenced by external forces, can alter the total angular momentum of the system. Thus, a slowly rotating swarm of particles, like a cloud of gas in space, if it contracts under its own gravitational attraction with attendant decrease in moment of inertia, must rotate the more rapidly to keep its angular momentum constant. Again, if a person, whirling about on tiptoe, with arms extended, suddenly brings the arms down to the sides, the individual will as suddenly begin to whirl faster, the effect being more pronounced if heavy weights are held in the hands. Angular momentum being a vector quantity, the principle applies as well to its direction as to its magnitude. The result is that any rotating body tends to maintain the same axis of rotation, a fact well illustrated by the spinning top and by the stabilizers used on some ocean vessels.

For an elementary or other particle, angular momentum may arise from (a) rotation about an axis, (b) revolution in an orbit, or from both (a) and (b). The angular momentum of rotation is called intrinsic angular momentum, or spin. When a nucleus is considered as a single particle, its total angular momentum is also referred to as its spin. For an elementary particle, the component in a particular direction of both kinds of angular momentum is quantized; the quantum of spin angular momentum is $\frac{1}{2}$, and the quantum of orbital angular momentum is.

ANGULAR VELOCITY AND ANGULAR ACCELERATION. These are quantities relating to rotational motion. While the use of the term "angular velocity" may be extended to any motion of a point with respect to any axis, it is commonly applied to cases of rotation. It is then the vector, whose magnitude is the time rate of change of the angle θ rotated through, i.e., $d\theta/dt$, and whose direction is arbitrarily defined as that direction of the rotation axis for which the rotation is clockwise. The usual symbol is $\boldsymbol{\omega}$ or $\boldsymbol{\Omega}$.

The concept of angular velocity is most useful in the case of rigid body motion. If a rigid body rotates about a fixed axis and the position vector of any point P with respect to any point on the axis as origin is $\mathbf{r}$, the velocity $\mathbf{v}$ of P relative to this origin is $\mathbf{v} = \boldsymbol{\omega} \times \mathbf{r}$, where $\boldsymbol{\omega}$ is the instantaneous vector angular velocity. This indeed may serve as a definition of $\boldsymbol{\omega}$.

The average angular velocity may be defined as the ratio of the angular displacement divided by the time. In general, however, this is not a vector, since a finite angular displacement is not a vector. The instantaneous angular velocity is more widely used.

Angular velocities, like linear velocities, are vectorially added; for example, if a top is spinning about an axis that is simultaneously being tipped over toward the table, the resultant angular velocity is the vector sum of the angular velocities of spin and of tipping. (This enters into the theory of precession.)

Angular acceleration is the time rate of change of the angular velocity, expressed by the vector derivative $d\boldsymbol{\omega}/dt$. Only in case the direction of the axis remains unchanged can the angular velocity and angular acceleration be treated as scalars. The effect of torque applied to a body free to rotate about an axis is to give it angular acceleration, and the opposition offered by the body to this process gives rise to the concept of moment of inertia. See also **Stroboscope**; and **Velocity and Speed Measurement**.

ANHEDRAL. Minerals in igneous rocks that are not bounded by their typical crystal faces are said to be anhedral.

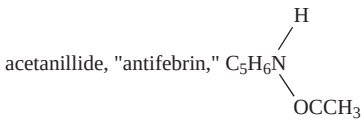
ANHYDRIDE. A chemical compound derived from and acid by elimination of a molecule of water. Thus, sulfur trioxide, SO_3, is the anhydride of sulfuric acid; CO_2 is the anhydride of carbonic acid; phthalic acid, $C_6H_4(CO_2H)_2$ minus water gives phthalic anhydride. The term should not be confused with *anhydrous*.

ANHYDRITE. The mineral anhydrous calcium sulfate, $CaSO_4$, occurs in granular, scaly, or fibrous masses, is rarely crystallized in orthorhombic tabular or prismatic forms. Hardness, 3–3.5; sp gr, 2.9–2.98; translucent to opaque; streak white; color, white, gray, bluish, or reddish. Anhydrite has three cleavages at right angles to one another. It is similar to gypsum and occurs under the same conditions, often with the latter mineral. It is usually found in sedimentary rocks associated with limestones, salt, and gypsum, into which it changes slowly by the absorption of water. See also **Gypsum**.

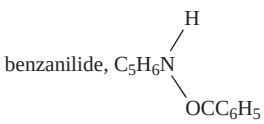
Anhydrite is found in Poland, Saxony, Bavaria, Württemberg, Switzerland, and France; in the United States, in South Dakota, New Mexico, Texas, New Jersey, and Massachusetts; in Canada, in Nova Scotia, New Brunswick, and exceptional specimens from the Faraday Uranium Mine near Bancroft, Ontario.

ANHYDROUS. Descriptive of an inorganic compound that does not contain water either adsorbed on its surface or combined as water of crystallization. Do not confuse with *anhydride*.

ANILINE. Aniline, phenylamine, aminobenzene, $C_6H_5NH_2$, is a colorless, odorous liquid, an amine, with melting point $-6\,^\circ C$, boiling point $184\,^\circ C$, is slightly soluble in water, miscible in all proportions with alcohol or ether, poisonous, turns yellow to brown in the air, is a weak base forming salts with acids, e.g., anilinehydrochloride ("aniline salt," $C_6H_5NH_2{\cdot}HCl$) from which aniline is reformed by addition of sodium hydroxide solution. Aniline reacts (1) with hypochlorite solution, to form a transient violet coloration, (2) with nitrous acid (a) warm, to form nitrogen gas plus phenol, (b) cold, to form diazonium salt (benzene diazonium chloride, $C_6H_5N{-}Cl$), (3) with acetyl chloride, acetic anhydride, or acetic acid glacial, to form N-phenylacetamide



(4) with benzoyl chloride, to form N-phenylbenzamide



(5) with benzenesulfonyl chloride, to form N-phenylbenzene sulfonamide, $C_6H_5SO_2NHC_6H_5$, soluble in sodium hydroxide, (6) with chloroform, $CHCl_3$, plus alcohol plus sodium hydroxide, to form phenyl isocyanide, C_6H_5NC, very poisonous, (7) with H_2SO_4 at 180° to $200\,^\circ C$, to form para -aminobenzene sulfonic acid (sulfanilic acid, $H_2N{\cdot}C_6H_4{\cdot}SO_2H$ (1,4)), (8) with HNO_3, when the amine group is protected, e.g., using acetanilide, to form mainly paranitroacetanilide, $CH_3CONH{\cdot}C_6H_4{\cdot}NO_2$ (1.4), from which paranitroaniline, $H_2N{\cdot}C_6H_4{\cdot}NO_2$(1,4) is obtained by boiling with concentrated hydrochloric acid, (9) with chlorine in an anhydrous solvent, such as chloroform or acetic acid glacial, to form 2,4,6-trichloroaniline (1) $H_2N{\cdot}C_6H_2Cl_3$(2,4,6), (10) with bromine water, to form white solid 2,4,6-tribromoaniline, (1)$H_2N{\cdot}C_6H_2Br_3$(2,4,6), (11) with potassium dichromate in sulfuric acid, to form aniline black dye, and, by further oxidation, benzoquinone, $O{:}C_6H_4{:}O$ (1,4), (12) with potassium permanganate in sodium hydroxide, to form azobenzene, $C_6H_5N{:}NC_6H_5$, along with some azoxybenzene $C_6H_5NO{:}NC_6H_5$, (13) with reducing agents, to form aminohexahydrobenzene (cyclohexylamine, $H_2N{\cdot}C_6H_{11}$), (14) with alkyl halides or alcohols heated, to form alkyl anilines, e.g., methylaniline, $C_6H_5NHCH_3$, dimethylaniline, $C_6H_5N(CH_3)_2$.

Aniline may be made (1) by the reduction, with iron or tin in HCl, of nitrobenzene, and (2) by the amination of chlorobenzene by heating with ammonia to a high temperature corresponding to a pressure of over 200 atmospheres in the presence of a catalyst (a mixture of cuprous chloride and oxide). Aniline is the end-point of reduction of most mono-nitrogen substituted benzene nuclei, as nitrosobenzene, beta-phenylhydroxylamine, azoxybenzene, azobenzene, hydrazobenzene. Aniline is detected by the violet coloration produced by a small amount of sodium hypochlorite.

Aniline is used (1) as a solvent, (2) in the preparation of compounds as illustrated above, (3) in the manufacture of dyes and their intermediates, (4) in the manufacture of medicinal chemicals. See also **Amines**.

ANIMALCULE. A minute animal. Applied to the protozoa and to such microscopic forms as the rotifers. See also **Rotatoria**.

ANIMAL UNIT. A term sometimes used in pasture and forage land management. One animal unit equals one mature cow, or one horse, or five sheep, or two yearling calves.

ANIMAL-UNIT-MONTH. The feed or forage needed to support one animal unit (see **Animal Unit**) for 30 days. One animal-unit-month is roughly equivalent to 0.3 ton (0.27 metric ton) of hay, or 300 pounds (135 kilograms) of total digestible nutrients.

ANIMATION CODEC. See **Data Compression**.

ANION. A negatively-charged atom or radical. In electrolysis, an anion is the ion which deposits on the anode; that portion of an electrolyte which carries the negative charge and travels against the conventional direction of the electric current in a cell. Within the category of anions are included the nonmetallic ions and the acid radicals, as well as the hydroxyl ion, OH^-. In electrochemical reactions, they are designated by the minus sign placed above and after the symbol, such as Cl^- and SO_4^{2-}, the number of the minus sign indicating the magnitude, in electrons, of the electrical charge carried by the anion. In a battery, it is the deposition of negative anions that makes the anode negative. See also **Ion**.

ANION-EXCHANGE RESINS. See **Ion-Exchange Resins**.

ANISE. Of the family *Umbelliferae* (carrot family), the anise plant (*Pimpinella anisum*) is native to the Mediterranean region and is cultivated in Egypt, Malta, Spain, and Syria, but also in other areas of the world, such as Germany and the United States. (This plant should not be confused with *fennel* or *finocchio*, which is commonly called anise in the marketplaces of the United States.)

Frequently, the plant is grown by gardeners of small plots as part of an herb garden. The plant achieves a height of about 2 feet (0.6 meter) with several slender branches. See Fig. 1. The aromatic, warm, and sweetish odor and taste of the seed, leaves, and stem arises from the presence of a volatile oil that contains anethole (*p*-propenyl phenylmethyl ether, $C_3H_5C_6H_4OCH_3$), the derivatives of which (anisole and anisaldehyde) are used in food flavoring, particularly bakery, liqueur, and candy products, as well as ingredients for perfumes. For commercial production of anise oil, the seeds and the dried, ripe fruit of the plant are used. Anise oil, a colorless to pale-yellow, strongly refractive liquid of characteristic odor and taste, is prepared by steam distillation of the seed and fruit. The oil contains choline, which finds use in medicine as a carminative and expectorant.

Fig. 1. Anise plant (*Pimpinella anisum*.)

The anise plant is an annual, planted directly from seed in the spring. The leaves of the plant can be used directly in salads to provide a distinctive flavor.

The fruit of a small evergreen tree (*Illicium anisatum*) of the Magnolia family is the source of *star* or *Chinese anise*. The aromatic and chemical characteristics of this plant are similar to those of *Pimpinella anisum* and thus there are similar uses for it.

ANISODESMIC STRUCTURE. A type of ionic crystal in which some of the ions tend to form tightly bound groups, e.g., nitrate and chlorate.

ANISOTROPIC MEDIUM. An anisotropic medium has different optical or other physical properties in different directions. Wood and calcite crystals are anisotropic, while fully annealed glass and, in general, fluids at rest are isotropic.

ANNABERGITE. The mineral annabergite is a rather rare nickel arsenate with the formula $Ni_3(AsO_4)_2 \cdot 8H_2O$, crystallizing in the monoclinic system. It is of secondary origin, resulting from the alteration of preexisting nickel minerals, commonly found as surface alteration crust on nickeline. Annabergite has been found in Saxony, France, including Annaberg, from which its name is derived, and as exceptional crystals at Laurium, Greece, and in Cobalt, Ontario, Canada.

ANNATTO FOOD COLORS. These colors are natural carotenoid colorants derived from the seed of the tropical annatto tree (*Bixa orellana*). The surface of the seeds contains a highly colored resin, consisting primarily of the carotenoid *bixin*. The bixin is extracted from the seed by a special process to produce a pure, soluble colorant. Bixin, one of the relatively few naturally occurring *cis* compounds, has a chemical structure similar to the nucleus of carotene with a free and esterified carboxyl group as end groups. Its formula is $C_{25}H_{30}O_4$. (See Fig. 1).

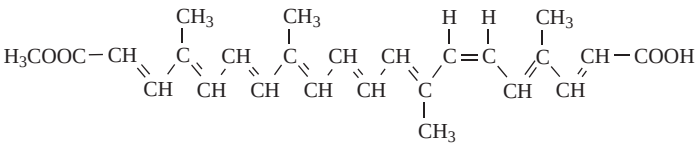


Fig. 1. Structure of bixin.

Bixin is an oil-soluble, highly stable coloring ingredient. The saponification of the methyl ester group to form the dicarboxylic acid yields the water-soluble form of bixin, sometimes called *norbixin*. Annatto colorants date back into antiquity. The colorant has been used for centuries in connection with various textiles, medicinals, cosmetics, and foods. Annatto colors have also been used to color cheese, butter, and other dairy products for over a century. See also **Carotenoids**.

Processors make annatto colors available as a refined powder, soluble in water at pH values above 4.0 (solubility about 10 grams in 100 milliliters of distilled water at 25 °C), in an acid-soluble form, in an oil-soluble form, in a water- and oil-soluble form, and in a variety of hues ranging from delicate yellows to hearty orange. Annatto extract is frequently mixed with turmeric extract to obtain various hues.

ANNEALING. The process of holding a solid material at an elevated temperature for a specified length of time in order that any metastable condition, such as frozen-in stains, dislocations, and vacancies may go into thermodynamic equilibrium. This may result in re-crystallization and polygonization of cold-worked materials.

Annealing generally falls into the technology of heat treatment and varies with materials and the intended end uses of the materials, as well as the prior processing of them. In the case of nonferrous alloys, annealing is primarily a heat treatment for the purpose of removing the hardening due to cold work. Annealing also may be used with nonferrous precipitation hardening alloys to cause softening through agglomeration of the hardening constituent into fewer and larger particles.

Ferrous Metallurgy. In the case of ferrous materials, the term annealing usually implies full annealing. This heat treatment involves a change of phase inasmuch as the metal is heated into the austenitic region. Cooling slowly back to room temperature then develops a softened structure of pearlite and ferrite. The annealing of cold-worked metal is termed *process annealing*, wherein a change of phase is not involved. Annealing takes several forms in terms of the time-temperature relationships imposed upon the materials. *Box annealing, isothermal annealing, normalizing, patenting, spheroidize annealing*, and *stress relieving* are described under **Iron Metals, Alloys, and Steels**.

Annealing of Cold-Worked Metals. Ductile metals hardened by cold-working may be softened by annealing. Annealing is often an important intermediate step in producing metals by cold deformation. Thus, in the formation of fine wires through wire drawing, several intermediate anneals may be required. Annealing may also be the last production step when metal objects are desired in a final softened condition.

In general, cold working increases many-fold the dislocation density of a metal. A severely cold-worked metal may easily have a dislocation density 10^6 times greater than in the same unworked metal. Since each dislocation is surrounded by a strain field extending over long distances on an atomic scale, each dislocation contributes to the strain energy of the metal and, accordingly, to its free energy. When the metal is annealed, the free energy associated with the dislocations resulting from cold work furnishes a driving force that can effectively reduce the dislocation density back to the value that existed before deformation.

Three basic stages are generally recognized as occurring during the annealing of cold worked metals. These are recovery, re-crystallization, and grain growth.

In recovery, the strain energy is lowered by the recombination of dislocations of opposite sign, or by rearrangements of dislocations into configurations of lower strain energy. A simple well-known example of this latter is the polygonization of the dislocations in a bent crystal. When a crystal is bent, the curved shape is the result of the accumulation, upon the slip planes of the crystal, of a large number of edge dislocations of the same sign. During recovery, these dislocations move from their more or less random positions along the slip planes into a set of vertical walls normal to the slip planes. This movement is accomplished by both slip and dislocation climb. The walls of dislocations that are formed in this manner constitute a form of grain boundary across which the crystal lattice is slightly rotated by the order of minutes of arc. Such boundaries are better known as sub-grain boundaries. The crystalline material between these sub-boundaries is effectively free of dislocations. It is thus apparent that polygonization transforms a highly strained bent crystal into a set of small sub-grains that are nearly strain-free. (See Fig. 1.)

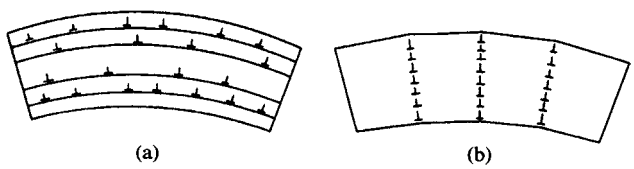

Fig. 1. Realignment of edge dislocations during polygonization: **(a)** excess edge dislocations that remain on active slip planes after a crystal is bent: **(b)** arrangement of dislocations after polygonization.

The rate of recovery is normally highest at the start of an isothermal annealing cycle because the driving force is largest at that time. As recovery continues, the driving force diminishes as the available strain energy is used up and the rate of recovery falls continuously toward zero. A plot of the rate of recovery as a function of time yields a curve that is somewhat similar in appearance to an exponential decay curve. The rate of recovery is also temperature dependent and may be expressed, in a number of cases, by a simple empirical equation of the form

$$1/t = Ae^{-Q/RT}$$

where t is the time to attain a certain fixed amount of recovery, A is a constant, R, the universal gas constant, T, the absolute temperature, and Q, an empirical activation energy. Because the reactions that occur during recovery are complex, it is usually not possible to attach a simple meaning to the activation energy for recovery.

Re-crystallization is the process whereby the distorted grains or crystals of a cold-worked metal are reconverted into new (essentially) strain-free grains. It occurs by the nucleation of minute submicroscopic crystals that grow out into and consume the strained material surrounding them. Re-crystallization is, therefore, a nucleation and growth phenomenon and, characteristically, the rate of re-crystallization starts slowly, builds up to a maximum, and then diminishes back to zero. The increase in the rate at the early stages of re-crystallization is due primarily to continued nucleation of new grains while the older ones continue to grow. The final falling off in the rate is the result of the progressive consumption of the material available for re-crystallization. A metal is said to be completely re-crystallized when all of the original deformed structure has been eliminated.

Re-crystallization, like recovery, is thermally activated and occurs at a rate that grows very rapidly with increasing temperature, as may be seen

in the accompanying diagram where the amount of re-crystallization in copper is plotted as a function of the time for six different temperatures. (See Fig. 2.)

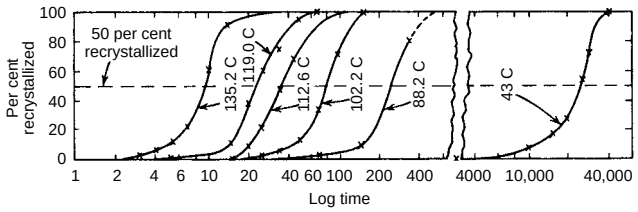

Fig. 2. Complex polygonized structure in a single silicon-iron crystal deformed 8% by cold rolling before being annealed 1 hour at 1100 °C.

The driving force for re-crystallization also comes from the strain energy of the excess dislocations created by cold work. It is therefore apparent that recovery and re-crystallization are competitive processes. Usually a metal may undergo a considerable degree of recovery before visible evidence of re-crystallization is obtained. However, since the re-crystallized grains grow from very small beginnings, the re-crystallization process undoubtedly is occurring long before it can be detected visually. Also, there is reason to believe that the nuclei of the re-crystallized grains may be formed as a result, at least in some cases, of processes related to recovery. It should also be noted that recovery phenomena may continue to occur during re-crystallization in those grains not yet consumed by the re-crystallization process. The degree to which the manifestations of re-crystallization and recovery appear to overlap is a function of the metal concerned and of the nature of the deformation that it has received. Under certain conditions, it is possible to have recovery occur without re-crystallization. This is particularly true when the amount of deformation is insufficient to cause re-crystallization, or when the type of deformation, although extensive, is very simple, as in the case of a zinc or magnesium crystal deformed only by slip on the basal plane. Examples have been observed where single crystals of these metals have been deformed in this manner by as much as 700% and still failed to re-crystallize on annealing.

After a metal has undergone re-crystallization it can still undergo grain growth. The driving force in this case comes from the surface energy of the grain boundaries. A close analogy exists between the growth of grains in a metal during annealing and the growth of soap bubbles in soap froth. In the soap froth, a small bubble that finds itself surrounded by larger neighbors will normally have but a few sides convex toward the bubble center. This curvature produces a small but finite excess gas pressure inside the small bubble, which causes gas to diffuse through the bubble wall into the neighboring larger bubbles. The smaller bubble, consequently, grows smaller and disappears, while the larger ones surrounding it grow in size. At the same time, the average bubble in the froth must also grow in size. The same basic phenomenon occurs during grain growth in metals. In this case, the atoms from the smaller grains move across the grain boundaries and become part of the crystals of the larger grains. At all times a geometrically similar distribution of grain sizes exists in the metal, ranging from small to large, which promotes continued grain growth. However, as the average size increases, there is a corresponding decrease in the growth rate. This is easily understood in terms of the soap froth analogy because with an increase in bubble size there is a corresponding decrease in the average bubble wall curvature and in the pressure difference across bubble walls. It may also be shown that in soap froth the average bubble size should increase as the square root of the time. This one-half power law, however, is seldom observed during grain growth in a metal. Usually the grain growth exponent (power to which the time is raised) is much smaller than one half, signifying that the empirical growth rates are much lower than would be expected from the soap froth analogy. Several reasons may be proposed in explanation of this fact. The motion of grain boundaries is easily influenced by impurity atoms in solid solution, or present as small inter-metallic inclusions. In either case, the grain boundary mobility is lowered with a corresponding decrease in the value of the grain growth exponent.

Under the proper conditions, a limiting grain size may be attained in a metal at which point grain growth ceases. This is often true in very thin specimens when the average grain diameter approaches the thickness of the specimen. At this time, the grain boundary geometry becomes two-instead of three-dimensional which reduces the average curvature and hinders further growth. Alternatively, it is possible for grain boundaries to become so held up by the nonmetallic inclusions that further growth is prevented. This condition is only achieved after a critical grain size has been achieved.

Associated with the limiting grain size effect mentioned above is a phenomenon known as secondary re-crystallization. Sometimes, after a limiting grain size has been attained, a few grains may begin to grow again and may obtain very large sizes. This is actually not a true re-crystallization but rather an unusual manifestation of grain growth. This formation of a new set of very large grains in material where growth had apparently ceased is known as secondary re-crystallization.

Annealing of Glass. As with metals, glass is fabricated at high temperatures and is annealed to relieve stresses that would develop if the glass were permitted to cool in an uncontrolled fashion. If not annealed, products made from high-expansion glasses can break spontaneously as they cool freely in air. In annealing glasses, they are raised to an annealing point temperature and then cooled gradually to a temperature that is somewhat below the strain point. Usually, the rate of cooling within this range determines the magnitude of residual stresses after the glass arrives at room temperature. Once below the strain point, the cooling rate is limited only by any transient stresses that may develop. A typical time-temperature glass-annealing curve is shown in Fig. 3. Normally, glass for optical purposes is annealed much more slowly than commercial glassware to improve the optical homogeneity of the material. In the annealing process, glass normally is heated and held at a temperature slightly higher than the annealing point temperature and controlled cooling is effected to a

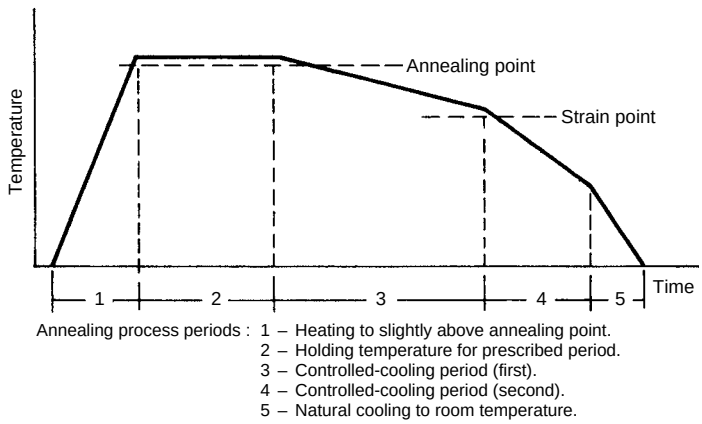

Fig. 3. Typical glass annealing curve.

temperature slightly below the strain point to accommodate for differences in materials and as an extra safeguard. Controlled cooling may occur over two periods as indicated by the diagram.

ANNELIDA. The segmented worms, including earthworms and leeches. This phylum is biologically interesting because it shows in a primitive form the structural plan of the more complex animals.

The annelids are characterized by: (1) metameric segmentation; (2) a closed tubular circulatory system in most forms; (3) a coelom; (4) an excretory system with tubules opening from the coelom to the exterior in various segments; (5) a tubular alimentary tract, with regions specialized for various functions; (6) a nervous system consisting of a dorsal brain above the esophagus, connected by cords passing around the esophagus, with a ventral chain of ganglia (see Ganglion) below the alimentary tract; (7) setae present in many species.

The annelids are classified as follows:

Class *Archiannelida*. Small marine annelids without setae; few to many segments.

Class *Polychaeta*. Worms with setae. No suckers. External segmentation distinct and metameric. Earthworms and many aquatic species.

Class *Oligochaeta*. Earthworms and many aquatic species.

Class *Hirudinea*. Flattened worms without setae but with a sucker at each end of the body. External segmentation consisting of 2–14 annuli to each metamere. Mostly aquatic, a few marine and a few terrestrial. Mostly blood-sucking parasites. The leeches.

ANNIHILATION. A term used in physics to describe a process in which a particle and antiparticle combine and release the energy associated with their rest masses. The most common example is the annihilation of an electron pair. Usually the negatron and the positron of the pair first form an atom of positronium from which state they merge and are annihilated. To conserve both energy and momentum the rest mass of this particle and antiparticle is converted into two photons moving in opposite directions, each with an energy of 0.511 MeV. The energy associated with the annihilation of other particle-antiparticle pairs, such as a proton and antiproton, is much larger than for an electron pair and is carried away by pions or kaons. See also **Particles (Subatomic)**.

ANNONA. Genus of the family *Annonaceae* (custard-apple family). This genus contains shrubs and small trees, many of which bear fruits consumed by humans. Generally, they are of relatively minor importance commercially, although some species are valued in regional markets and some are used to make purees, which find use in a variety of processed foods. These fruits are composed of many individual ovaries that are more or less sunk in the fleshy receptacle and united to it and to each other. In some species, these collective fruits are quite large — up to 8 inches (20 centimeters) in length. Some of the fruits are so heavy that they drag down the branches. In tropical areas where they are grown, the small fruit trees frequently attract ants, which must be destroyed, particularly during the fruiting season. The trees are susceptible to various fungus diseases, causing fruit rot. Copper-based fungicides are frequently used. *Annona* species are found in the tropics of both the northern and southern hemispheres.

Soursop. This species, *Annona muricata*, is found on the islands of the Caribbean Sea, in Florida, and in southeastern Asia, notably in Malaysia. The *A. muricata* is a small evergreen tree about the size of a peach tree. The leaves are leathery and malodorous. The fruit is large (8 inches; 20 centimeters in length) heavy, and pear-shaped, with a rough skin that has spine-like projections. The flesh is white, succulent, acidic, and is variously reported (depending upon particular variety) as having a rich flavor of wine, a taste reminiscent of the black currant, and a flavor something like that of a mango. The seeds are large and of a dark color. The tree has many branches, is decorative, and is valued as a garden ornament as well as for its fruit. In the United States, successful cultivation is confined essentially to southern Florida. The fruit can be found in the markets in the vicinity of Key West. The soursop is processed to remove seeds and fibers in preparation of a puree. This puree can be preserved by canning or freezing. It is then available for use as a base material for flavoring sherbets, ice creams, beverages, and other products. Prior to freezing, the puree is heated to a temperature of about 185 °F (85 °C) for a few minutes to inactivate peroxidase which, if present, may cause a pink discoloration and off-flavors. Sometimes soursop nectar is available in cans or bottles. The soursop is recommended by specialists at the Food and Agriculture Organization (United Nations) for inclusion in school and demonstration gardens in various developing tropical areas, such as found in west Africa.

Common Custard Apple. This species, *Annona reticulata*, is a deciduous tree that reaches a height of from 15 to 25 feet (4.5 to 7.5 meters). The tree is one of the more robust of the *Annona* species and is commonly found growing in the West Indies and many tropical and subtropical areas of the world. There are numerous trees of this species in southern Florida. The *A. reticulata* is an exception among the *Annona* species in that it spreads spontaneously and need not be individually planted. This widespread growth is exemplified by the profusion of the trees found in the forests of the Philippines, on the island of Guam, and in Malaysia. The fruit or custard apple is inferior in flavor and other edible characteristics as compared with the sugar apple and the cherimoya. The fruit is from 3 to 5 inches (7.5 to 12.5 centimeters) in diameter, has a smooth skin that is geometrically divided into rhomboid or hexagonal areoles. The color varies from red to reddish-brown when ripe. The pulp is semisweet with a tallowlike consistency. The seeds adhere tenaciously to the flesh.

Sweetsop or Sugar Apple. This species, *Annona squamosa*, is native to tropical America and does not do well in subtropical regions as will some of the *Annona* species. The plant is a small deciduous tree that attains a height of from 15 to 20 feet (4.5 to 6 meters). In addition to the West Indies, this species is found throughout the tropics in southern Asia and is particularly popular in India where locally it is called *custard apple*, a fact that tends to confuse it with the true custard apple previously described. The fruit is regarded more highly than *A. reticulata*. The sweetsop is much smaller than the soursop fruit, ranging from 2 to 3 inches (5 to 7.5 centimeters) in diameter and has an almost smooth, segmented skin. The flesh is fragrant and sweet to the taste. The pulp is a pale-yellow and looks very much like custard. Seeds are dark-brown. An advantage of this species is that it produces fruit throughout the year.

Cherimoya. This species, *Annona tripétala* Ait., is a larger tree, rising to a height of about 25 feet (7.5 meters) and more. It is commonly found in the Peruvian Andes and surrounding regions. The plant is also planted in Mexico, a number of Central American countries, Hawaii, India, the Canary Islands, and on the Island of Madeira. The cherimoyas of Madeira are well known and valued for their elegant flavor. In Madeira, the cherimoya plant is trained on trellises much as grapes are grown. The fruit is variously shaped — sometimes spheroidal, ovoid, conoid, and heart-shaped. A sometimes-used synonym for the fruit is *bullocksheart*. The fruit has a slightly mottled, comparatively smooth surface. The pulp is white with a pleasing acidulous taste. The seeds are easily separated from the pulp, an advantage in eating the fruit fresh as well as for processing. Over the last several decades, considerable success has been enjoyed in raising this species in California.

ANNUAL. A plant that normally completes its life cycle, from seed to seed, in a single growing season. Typical annuals are corn (maize), wheat, cucumber, and nasturtium. Annual plants are especially suited for life in regions where the growing season is short and alternates with an unfavorable cold period or dry season.

ANNUAL RING. A layer of wood added to the stem in one growing season. In temperate climates, stem growth occurs during the warm spring and summer months. The cells formed in spring when active growth is taking place are characteristically large, while during the summer only smaller cells are added. This alternation of cells results in the formation of definite concentric rings readily seen in cross sections of woody stems. Actually the growth increment is in the form of a sheath continuous over the entire stem except at the growing tips. External conditions may have a profound effect on the appearance of the annual ring; favorable growing seasons with ample moisture result in broad rings, while seasons of drought produce narrow rings. Removal of surrounding over-shading trees may result in a pronounced increase in the thickness of the annual ring. At times events such as severe defoliation by insects or cases of drought may produce two rings in one season; such rings are ordinarily not sharply distinct as are normal ones, and are called false annual rings. Counting of annual rings gives an accurate index of the age of the tree, while attention to details such as variable thickness of successive rings serves to indicate environmental changes. By careful comparison of different logs, even though they are largely reduced to charcoal, one may determine the actual year in which the ring was formed. By this means it has proved possible to establish the probable age of many ruins in the southwestern

states. In tropical countries having a continuous growing season, annual rings are not formed or are only slightly developed. If, however, alternating rainy and dry seasons occur, then they appear.

ANNULUS. In the sporangium of many ferns, a ring of cells which have their walls characteristically thickened, and bring about the violent discharge of the spores within. In agarics, the ring of tissue found around the stalk in many genera, is also known as an annulus.

ANNULUS (Geometry). See Circle.

ANODE. In the most general sense, an anode is the electrode via which current enters a device. The anode is the positively charged electrode of an electrolytic cell. See **Electrochemistry**. The anode (also frequently called the plate) is the principal electrode for collecting electrons in an electron tube, and is, therefore, operated at a positive potential with respect to the cathode.

ANODE SHEATH. In a gas discharge tube, the electron boundary that exists between the plasma and anode when the current demanded by the anode circuit is larger than the random electron current at the surface of the anode.

ANODIC OXIDATION. Oxidation is defined not only as reaction with oxygen, but as any chemical reaction attended by removal of electrons. Therefore, when current is applied to a pair of electrodes so as to make them anode and cathode, the former can act as a continuous remover of electrons and hence bring about oxidation (while the latter will favor reduction since it supplies electrons). This anodic oxidation is utilized in industry for various purposes. One of the earliest to be discovered (H. Kolbe, 1849) was the production of hydrocarbons from aliphatic acids, or more commonly, from their alkali salts. Many other substances may be produced, on a laboratory scale or even, in some cases, on an economically sound production scale, by anodic oxidation. The process is also widely used to impart corrosion-resistant or decorative (colored) films to metal surfaces. For example, in the anodization or Eloxal process, the protection afforded by the oxide film ordinarily present on the surface of aluminum articles is considerably increased by building up this film by anodic oxidation.

ANODIZE. This term means to place a protective film on a metal surface by electrolytic or chemical action in which the metal surface is made the anode in an electrochemical process. Aluminum and magnesium parts of electronics equipment are frequently anodized.

ANODIZED COATINGS. See **Conversion Coatings**.

ANOLIS *(Reptilia, Sauria)*. The name of a genus of lizards adopted also as a common name; small, mostly brightly colored lizards of the warmer latitudes of the Americas. The little lizard sometimes sold under the name chameleon is the Carolina anolis, *Anolis carolinensis*, and is a common species of the southern United States and southward.

ANOMALODESMACEA. An order of bivalve mollusks, mostly burrowing marine species.

ANOMALOUS COSMIC RAYS. While interstellar plasma is kept outside the heliosphere by an interplanetary magnetic field, the interstellar neutral gas flows through the solar system like an interstellar wind, at a speed of 25 km/sec. When closer to the Sun, these atoms undergo the loss of one electron in *photo-ionization* or by *charge exchange*. Photo-ionization is when an electron is knocked off by a solar ultra-violet photon, and charge exchange involves giving up an electron to an ionized solar wind atom. Once these particles are charged, the Sun's magnetic field picks them up and carries them outward to the solar wind termination shock. See Fig. 1. They are called *pickup ions* during this part of their trip. See also **Solar Wind**; and **Termination Shock**.

The ions repeatedly collide with the termination shock, gaining energy in the process. This continues until they escape from the shock and diffuse toward the inner heliosphere. Those that are accelerated are then known as anomalous cosmic rays.

It is not certain exactly which particles are accelerated at these shocks. The energy boost given to pickup ions at CIR (Corotating Interaction Regions) shocks may be an important factor in ACR production. The mechanism of the acceleration of pick-up ions at the solar wind termination shock is also a big question. See also **Heliosphere**.

ACRs are thought to represent a sample of the very local interstellar medium. They are not thought to have experienced such violent processes

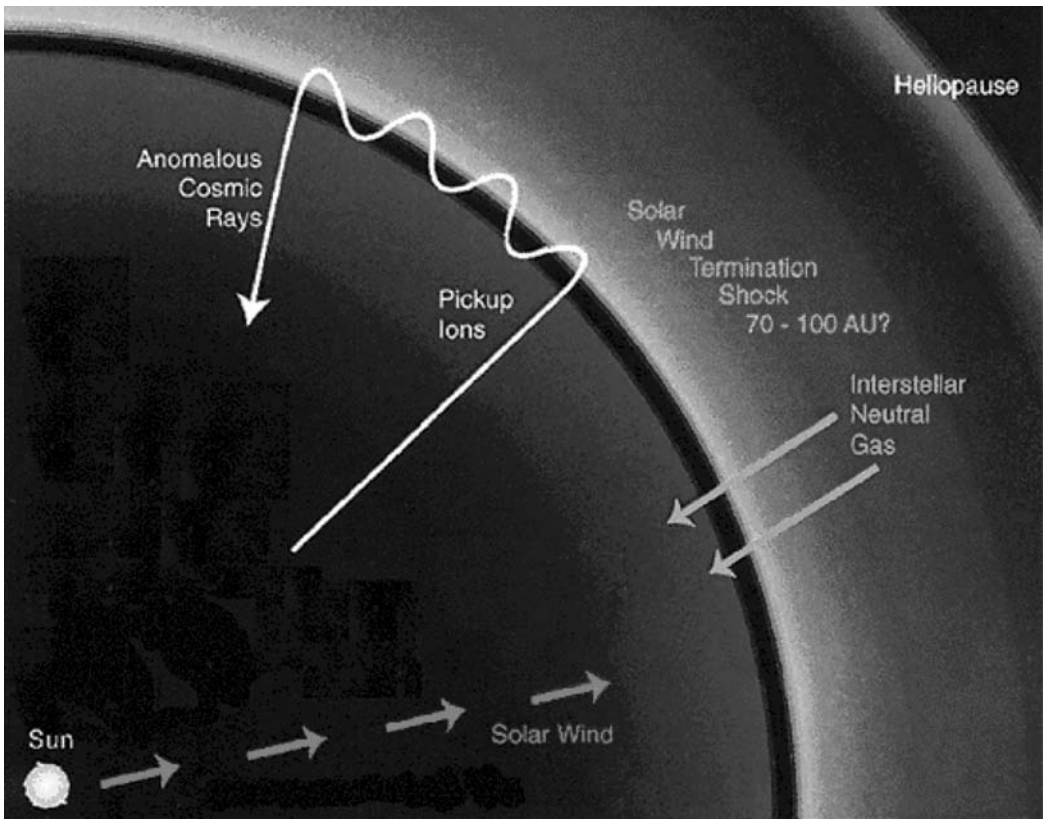

Fig. 1. Illustration showing formation of anomalous cosmic rays.

as GCRs, and they have a lower speed and energy. ACRs include large quantities of helium, oxygen, neon, and other elements with high *ionization potentials*, that is, they require a great deal of energy to ionize, or form ions. ACRs are a tool for studying the movement of energetic particles within the solar system, for learning the general properties of the heliosphere, and for studying the nature of interstellar material itself. See also **Cosmic Rays**; and **Interplanetary Medium**.

ANOMALOUS DISPERSION. Ordinarily the refractive index n of a medium decreases with increasing wavelength λ (see **Dispersion**). It often happens, however, that in the immediate vicinity of a certain wavelength λ_1 there is a break or discontinuity in the dispersion curve and the usual rule may be locally reversed (see Fig. 1). In some cases there are several such points, $\lambda_1, \lambda_2, \lambda_3, \ldots$. These discontinuities correspond to lines or bands in the absorption spectrum of the medium. In the Sellmeier equation

$$n = 1 + \frac{A\lambda^2}{\lambda^2 - \lambda_1^2} + \frac{B\lambda^2}{\lambda^2 - \lambda_2^2} + \ldots$$

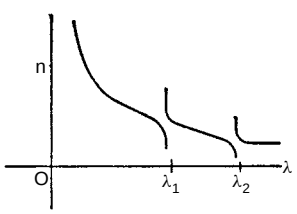

Fig. 1. Variation of refractive index with wavelength, illustrating anomalous dispersion.

the several fractional terms make provision for the respective discontinuities. The absorption wavelengths $\lambda_1, \lambda_2, \ldots$ and the constants $A, B, \ldots$ must be determined experimentally. It will be noticed that n becomes infinite at every wavelength λ_k and is finite at all other wavelengths. If there is pronounced absorption and anomalous dispersion in the visible range, the medium appears colored, as illustrated by transparent dyes.

ANOMALOUS PROPAGATION. The propagation of energy when it arrives at a destination via a path significantly different from the normally expected path. The term is usually applied to the transmission of various forms of energy through the atmosphere when, in addition to the line-of-sight path, the energy is refracted by density discontinuities at one or more levels in atmosphere. Therefore, it propagates to a point that could not be reached via a line-of-sight path. In radio and radar studies, it refers to the abnormal refraction of a beam of radio energy, usually applied to superstandard propagation rather than to substandard propagation. In either case, anomalous propagation results from an unusual vertical distribution of temperature and moisture in the atmosphere.

The anomalous propagation of sound refers to the downward refraction of an oblique sound wave from an explosion, the refraction occurring in the region of increasing temperature with height in the lower mesosphere. The anomalous propagation of sound has been used as a method for determining upper air temperatures and winds. See also **Atmosphere (Earth)**; and **Radio Duct**.

ANOMALOUS REFRACTION. Literally, refraction that is not normal or typical. Anomalous or abnormal is frequently used to characterize the conditions that give rise to mirages, such as in this example: "Abnormal refraction responsible for mirages is invariably associated with abnormal temperature distributions that yield abnormal spatial variations in the refractive index." Yet mirages and the conditions that give rise to them are very common. It would appear that, when these terms are used, normality is something defined by the free atmosphere, far from surfaces. Certainly, by that measure, the refractive index gradients near a surface are abnormal. It is misleading to imply that either the refractive structures or the mirages are abnormal or anomalous when they are so common near the earth's surface, merely because they are not as common farther away from that surface. See also **Atmospheric Optical Phenomena; Refraction**; and **Refractive Index**.

ANOMALY. 1. The deviation of (usually) temperature or precipitation in a given region over a specified period from the long-term average value for the same region. 2. In geophysics, the local deviation from the long wavelength trend, as magnetic anomaly or gravity anomaly.

ANOMALY (Oceanography). The difference between the conditions actually observed at a particular point of measurement and an ocean of standard or arbitrary temperature and salinity.

ANOPLURA. The order of insects that includes the true or sucking lice. They are wingless parasitic insects with mouths formed for piercing and sucking.

ANOREXIA. A loss of appetite or distaste for food, present for short periods in connection with a variety of diseases, is known as *anorexia*. Anorexia and weight loss frequently occur among patients with cancer and also arises in chronic alcoholism. The conditions may be due directly to the presence of the tumor in some cases. Anorexia may arise because of the production of anorexigenic peptides, a negative nitrogen balance as the result of unreutilized tumor amino acids, an uncoupling of oxidative phosphorylation, or a degraded glucose tolerance. Frequently, anorexia and weight loss are manifestations of the psychological and emotional stresses of a malignancy. Anorexia is almost universally present in subacute bacterial endocarditis. Usually where anorexia arises from a physical disorder that can be cured or arrested, the patient's appetite will ultimately return.

In some animals, particularly those species that hibernate, anorexia is naturally programmed. Fasting during hibernation has been recorded for centuries. However, more recent studies have shown that some animals eat very little and lose weight even when food is available. Often, this occurs when there are other more important activities that compete for the animal's time and attention. An example is that of bull seals that go without feeding for many weeks while minding their duties of defending territory and harem. Fasting associated with incubation, migration, and molting, as well as hibernation, also have been documented over a period of years. Some authorities believe that possibly through hormonal controls some species preprogram periods of anorexia that are made to coincide with other natural actions of greater importance at certain times for survival of individuals and preservation of species. In studies of this behavior, quite limited to date, no information has been uncovered that may be helpful toward understanding and treating the serious human disorder *anorexia nervosa*, which is described next. However, some early keys to improved control of obesity among humans are beginning to unfold.

Anorexia Nervosa. This disease has probably been best described as a complex psycho-endocrine disorder. This is a serious disease, with fatality rates ranging from 2 to 21%, as estimated by various authorities with death in many cases being suicidal. Currently the disorder is poorly understood and statistics are not fully reliable or representative. For example, the rate of incidence of the disease is not accurately known.

The core clinical features of Anorexia Nervosa include:

1. Refusal to maintain a minimum average body weight (often defined as a BMI of less than (8));
2. Distorted body image (e.g., a fear of fatness or feeling fat even when emaciated); and
3. In females, amenorrhea.

Although emaciation is the most visible indication of anorexia nervosa, patients are also recognizable for their unusual eating habits, excessive exercise, and in some cases, the presence of a fine growth of hair on their body.

Amenorrhea may be present at the outset or develop during the course of the disorder. Although the illness includes an endocrine disturbance, it is specific and confined to the hypothalamic-anterior pituitary-gonad axis. In the absence of hypothalamic defects, the general view is that endocrine changes follow rather than lead the psychological and emotional oddities of the disease. The disease has not been established as having an endocrine origin, but does cause serious endocrine consequences.

Fatness is intolerable to such patients. Sometimes a precipitating experience, difficult to comprehend by others, may be perceived by the patient as the trigger of the motivation to be thin. The loss of weight induced by the prolonged insufficient intake of carbohydrates is self-induced and thought to be a protective device. Dread of growing up, leaving home, and becoming independent have all been associated with development of the disease which, although most common in the upper social classes, does not exempt any social strata. Most patients with anorexia nervosa are not considered psychotic. Sometimes, however, anorexia nervosa is part of the complex in a true mental illness. Patients tend to be normal in their approach to life excepting the topics of food and weight. It is not unusual for such patients to prepare nutritious meals for the consumption of others. Although the distinctive features of anorexia nervosa are easy to detect, examinations generally reveal few abnormalities except those of an endocrine nature. There are atypical cases that do make diagnosis difficult. Some of the aforementioned criteria may be absent or only partly present.

Therapy includes psychotherapy, family therapy, hospitalization, the course of treatment taking some two to three years with many opportunities for relapse. Numerous drugs have been used, but reliable comparative studies have not shown any one drug to be the treatment of choice.

Recovery is uncertain and varies with individuals. Limited statistics indicate that about 48% of patients ultimately recover, including a return of menses, normal weight, and improved mental and psychosexual outlook. Intermediate results have been reported in 30% of cases; very poor results in 20% of cases.

In patients with hypothalamic defects, the most frequent mechanism of secondary amenorrhea is the absence of the LH (leutenizing hormone) required for ovulation. One of the most vulnerable components of the female reproductive endocrine system, the LH surge is inhibited in anorexia nervosa.

Delayed puberty may result from prepubertal anorexia nervosa. Persons with anorexia nervosa, as well as persons who have voluntarily (martyr syndrome) or involuntarily starved may develop leukopenia and neutropenia — low blood counts of white cells and neutrophils, respectively. See also **Eating Disorders**.

ANORTHOSITE. The name anorthosite was given by T. Sterry Hunt to rocks of gabbroid nature which were essentially free from pyroxene, hence almost wholly plagioclase *usually* labradorite. The term is derived from the French word for plagioclase, anorthose. Small quantities of pyroxene may be present as well as magnetite or ilmenite. The rock is commonly white to gray, bluish, greenish, or perhaps nearly black. A variety from the Province of Quebec is purplish-brown due to the inclusion of ilmenite dust within the feldspars. Although not a common rock in the ordinary sense of the word, occurrences of great territorial extent are known in Canada, Norway, and Russia and in the United States in northern New York State and Minnesota. Opinions as to the origin of this rock differ. The development of anorthosite may have been due to the settling out of labradorite crystals from a gabbro magma as many believe, or there may have been an original anorthosite magma.

A study of anorthosite occurrences brings out two very curious circumstances, first, that there is no extrusive (lava) equivalent of anorthosite, and second, that most anorthosite masses seem to be of pre-Cambrian age.

ANOXEMIA. Deficiency in the oxygen content of the blood. This may be reduced:

1. When there is insufficient oxygen available to saturate the hemoglobin; this may occur in pulmonary diseases in which inflammatory processes interfere with the passage of oxygen into the blood, or under conditions encountered in high-altitude climbing, inhalation of inert gases (methane, helium), in which there is insufficient oxygen in the inhaled air, and in the late stages of cardiac and respiratory disease when insufficient air is inspired (anoxic anoxemia);

2. When the amount of hemoglobin in the blood is insufficient to carry the amount of oxygen required, as occurs in anemia from any cause, especially that following acute or chronic blood loss (anemic anoxemia).

Rapidly developing anoxemia leads, when the oxygen tension of the inspired air (normally 21%) falls to 10%, to cyanosis and to increased rate and depth of breathing; at 5% to loss of consciousness and ultimate death.

Slowly developing anoxemia may be compensated for by a process of acclimatization, not however without damage to vital tissues when the oxygen deprivation is prolonged.

ANSERIFORMES *(Aves).* A large number of goose-like or fowl-like birds that live near water and at least temporarily go into water are grouped in this order. They are ground and water birds; the length is 28–170 centimeters (11–67 inches), and the weight is 200–13,500 grams (7 ounces to 30 pounds). The nostrils connect with one another, and the lower mandible has a long process at the angle. The sternum has two indentations or two foramina at the rear; these are absent in the fossil giant duck (*Cnemiornis*) of the glacial period. Two pairs of muscles are located between the sternum and the trachea. The neck is extended in flight. There are 10–11 primaries, the fifth secondary is absent (diastataxic wing), and there are 12–24 tail feathers. Many down feathers are found in the fully developed plumage. The unspotted eggs are light in color. The young are nidifugous, have a dense downy plumage, and are tended for a long time by one or both parents. They are distributed over all continents except Antarctica. The *Anseriformes* are divided into two families distinguished by the absence or presence of horny lamellae in the beak: (1) screamers (*Anhimidae*), and (2) ducks and geese (*Anatidae*).

The screamers (family *Anhimidae*) are almost goose-sized birds of fowl-like appearance, with fairly thick, long legs and feet without webs. The weight is 2–3 kilograms (4.4–6.6 pounds).

There are two genera with marked differences in their internal structure: the horned screamers (*Anhima*), with 14 tail feathers, and the crested screamers (*Chauna*) with 12 tail feathers. Altogether, there are three species, with no subspecies: (1) the horned screamer (*Anhima cornuta*), which reaches a length of 80 centimeters (31 inches) and inhabits the flood forests of the Amazon delta, (2) the crested screamers (*Chauna torquata*), with a length of 90 centimeters (35 inches), found in swampy pampas

areas of the La Plata States, and (3) the black-necked screamer (*Chauna chavaria*), with a length of 70 centimeters ($27\frac{1}{2}$ inches), found on forest rivers of Colombia and Venezuela.

Outside the breeding season, the horned screamers live in troops of 5–10 birds. The crested screamers are, however, found in larger flocks that circle above the waters in their habitats in the evenings, calling melodiously. In contrast to the *Anatidae*, they can glide well. In spite of their unwebbed feet, screamers swim very well; the crested screamer will even climb onto the leaves of floating plants from the shore. These birds calmly walk about the shore or in shallow water; their food is entirely vegetarian and they obtain some of their food while swimming. They readily perch on the branches of trees and, when disturbed or pursued, generally take to trees.

All other members of this order are included in the family of ducks and geese (*Anatidae*). They have horny lamellae on the interior of the beak near the cutting edge. There are webs between the anterior toes. The upper mandible has a particularly hard process, the "nail," at its tip. There are large nasal cavities; because of this, geese breathe faster when reacting to olfactory stimuli. There are 16–25 cervical vertebrae. They cannot soar or glide to any extent; a few species are flightless, while others have a rapid flight.

There are three subfamilies: (1) the magpie goose (*Anseranatinae*) with only minute webs, (2) the geese and relatives (*Anserinae*) with larger webs and small scales on the tarsus and toes, and (3) the ducks and their relatives (*Anatinae*), which also have large webs.

The *Anatidae* are made up of many species that are colorful and of many shapes. There is a wide range of changing forms and ways of life, from the minute African pigmy geese to the trumpeter swan, which weighs $13\frac{1}{2}$ kilograms (30 pounds), and from the inconspicuous greylac goose to the colorful plumage of the king eider. Nevertheless, the different species have common characteristics that justify their grouping in one family. Thus all are water birds, even species which live mainly on land like the Cape Barren goose and the Hawaiian goose. Since, as swimmers, their plumage must always be greased, they have a particularly large preen gland.

All *Anatidae* have webbed feet. The webs extend from the second to the third and from the third to the fourth toe. *Anatidae* do not have to make any particular effort to remain on the surface of the water or to swim. Their buoyancy is due mainly to the air held in the plumage. They take great care not to get water under their plumage. The closed wing is covered by feathers projecting up from the side of the breast so that, of the wing feathers, only the scapulare and the primaries are generally exposed. The body plumage is continually and carefully covered with oil from the preen gland and so forms a layer impermeable to water.

A particular adaptation to the requirements of swimming is the broad cross section of the body of most *Anatidae*. This broad, bargelike body maintains its balance despite wind or waves. Another adaptation is the shortening of the thigh and tarsus. The tarsus functions like the arm of a lever in swimming, and in slow swimming is almost the only part of the leg that moves. Only in faster swimming is the thigh involved as well; it is drawn back with partially extended knee, the lower leg serving merely to transmit power.

To reduce resistance to the water when the tarsus moves forward, the webs and toes are folded together and the toes are bent. In pushing back, the toes and webs are fully extended and form an effective oar-like surface. As in walking, so in swimming the legs move alternately. Only the mute swan in its aggressive display swims with jerky movements, pushing back with both legs at the same time; however, it swims no faster by this method.

According to their manner of obtaining food, the *Anatidae* can be divided into several groups. Swans, shelducks, and surface feeding ducks "up end"; that is they immerse the head and neck with the rear of the body projecting almost upright above the water. In this way, they can feel over the bottom of shallow waters with the beak, and obtain food by straining it out of the water. Diving ducks also generally get their food from the bottom, but they reach greater depths and dive completely below the surface. Lastly the mergansers chase fish beneath the surface.

The true geese, swans, and whistling ducks are entirely vegetarian. Mergansers, scoters, eider ducks, and the South American torrent ducks take only animal food. The rest take both plant and animal food. The amounts of food taken are at times considerable. In the digestive tract of an eider duck, 114 mussels were found, some of which were already partially digested within their shells; the gullet and stomach of a velvet scoter contained 45 oysters.

Most of the species build their nests on the ground. Some of the genus *Tadorna*, like the common shelduck, prefer burrows in the ground as nest site, although some other species of ducks, among them the mallard, also nest on trees. The Orinoco goose, many of the *Cairini* like the maned wood duck, the mandarin, and the wood duck, the Brazilian teal, the pigmy geese, the comb duck and its relatives, the goldeneyes, and some mergansers breed preferably in tree cavities. Nests of the magpie goose, the coscoroba swan, and many diving ducks and stiff-tailed ducks are often found in dense swamp vegetation on the water.

The nest construction is simple. As far as it is possible, the birds make a hollow in the ground and pull in stems and leaves from around the nest site, as far as they can reach with their outstretched necks. All species cover incomplete clutches with plant material when leaving the nest. Shortly before the last egg is laid, the females pluck the nest-down and line the nest with it. See also **Poultry**; **Screamer**; and **Waterfowl**. Extensive information and excellent illustration of the vast variety of Anseriformes (Aves) can be found in "Grzimeks Animal Life Encyclopedia," Vol. 7 (Birds I), Van Nostrand Reinhold, New York, NY, 1972.

ANTACIDS. These are formulations widely used in the treatment of excessive gastric secretions and peptic ulcer. Several factors determine the efficacy of antacids, including (1) the ability and capacity of the stomach to secrete acid; (2) the duration of time the antacid is retained in the stomach; and (3) the nature of the gastric response upon eating.

Five principal active ingredients are used in antacid preparations: (1) *Sodium bicarbonate* is a rapid and effective neutralizer. The compound does yield large amounts of absorbable sodium, undesirable in some persons (heart disease; hypertension). The compound also may induce milk-alkali syndrome. (2) *Calcium carbonate* is a strong, effective neutralizer, but can cause constipation, hypercalcemia, acid rebound, and milk-alkali syndrome. (3) *Aluminum hydroxide* provides slow and not potent action. The compound causes constipation, absorbs phosphates, as well as certain drugs, such as tetracyclines. (4) *Magnesium hydroxide* which provides a slow and prolonged action with no major side reactions. (5) *Magnesium trisilicate* which acts like magnesium hydroxide, but which is poorly absorbed and acts as an osmotic laxative. In cases of renal insufficiency, the serum magnesium should be monitored.

The foregoing compounds are frequently used in combination and, in some, simethicone is added to relieve flatulence. There are striking differences of commercial antacids in terms of their neutralizing capacity.

The physician is concerned with at least three factors when prescribing antacids: (1) Acid rebound (associated with calcium carbonate); (2) milk-alkali syndrome (caused by ingestion of large quantities of alkali); and (3) phosphorus depletion (by aluminum salts). The mechanism of acid rebound, especially in the long-term use of calcium carbonate, is poorly understood. It has been established that there is an excessive re-acidification of the antrum (pyloric gland area) a number of hours after ingestion of calcium carbonate.

The ingestion of a quart of milk or more while taking large amounts of alkali, as from antacids, sets up conditions favorable to milk-alkali syndrome. Generally, with withdrawal of the milk or the antacid, the condition is self-correcting. Symptoms of milk-alkali syndrome include nausea, vomiting, anorexia, weakness, polydipsia, and polyuria. Abnormal calcifications also may occur in the chronic stage and other symptoms include mental changes, asthenia, aching muscles, band keratopathy, and nephocalcinosis. Symptoms of milk-alkali syndrome sometimes tend to mimic hyperparathyroidism and vitamin D intoxication.

ANTARATIC CIRCUMPOLAR CURRENT (ACC). See **Ocean Currents**.

ANTARCTIC CONVERGENCE. A distinct, natural oceanographic boundary around the continent of Antarctica. The boundary is more or less equivalent to the 50 °F (10 °C) isotherm for the warmest month. It has been determined that the colder, denser Antarctic waters sink sharply below the warmer, lighter Subantarctic waters with very little mixing. The
